ABSTRACT

Alzheimer’s disease (AD) is a scourge of longevity that will drain enormous resources from public health budgets in the future. Currently, there is no diagnostic biomarker and/or treatment for this most common form of dementia in humans. AD can be of early familial-onset or sporadic with a late-onset. Apart from the two main hallmarks, amyloid-beta and neurofibrillary tangles, inflammation is a characteristic feature of AD neuropathology. Inflammation may be caused by a local central nervous system insult and/or by peripheral infections. Numerous microorganisms are suspected in AD brains ranging from bacteria (mainly oral and non-oral Treponema species), viruses (Herpes simplex type I) and yeasts (Candida species). A causal relationship between periodontal pathogens/non-oral Treponema species of bacteria has been proposed via the amyloid-beta and inflammatory links.

Periodontitis constitutes a peripheral oral infection that can provide the brain with intact bacteria and virulence factors and inflammatory mediators due to daily, transient bacteraemias. If and when genetic risk factors meet environmental risk factors in the brain, disease is expressed, in which neurocognition may be exacerbated, leading to the of dementia. To achieve the goal of finding a diagnostic biomarker and possible prophylactic treatment for AD, there is an initial need to solve the etiologic puzzle contributing to its pathogenesis. This review therefore addresses oral infection as the plausible aetiology of late onset AD (LOAD), the plausible aetiology of the late-onset AD being an oral infection.

Keywords: Alzheimer’s disease; pathogenesis; microorganisms; oral bacteria; direct cause
Alzheimer’s disease (AD) is a neurodegenerative disease and the most common example of a group of diseases that manifest as dementia. It is associated with atrophy and specific neuronal death particularly in the hippocampal region of the brain (1). Research into AD pathogenesis, has flagged two main categories of the disease: familial-onset that accounts for around 2% of all AD cases and the sporadic form of late-onset AD also known as LOAD that constitutes approximately 98% of the cases. LOAD displays genetic susceptibility traits of which the well-known risk factor is inheritance of the apolipoprotein (APOE)4 gene allele (2) and, appears to require an environmental factor for disease expression. For example a pathogen-host interaction, can exacerbate neurocognition in some elderly individuals who if in their 80+ years likely become diagnosed with LOAD (3, 4). The rationale for this review therefore is to try to explain the aetiology in the vast proportion of LOAD cases that relies upon common risk factors, and to date, several scientists these to be peripheral infections (5-11), and the accompanying systemic and local inflammatory mediators (11-13). Of these, the plausible risk from oral infection is the main focus of this review.

PREVALENCE OF AD

AD is a scourge-burden of longevity resulting from the superior quality of health care. This factor is likely to contribute to quadrupling of AD subjects living in our society during the next 40 years (14). It is estimated that by 2050 about 13-14 million people are likely to suffer from AD in the USA with a rise in the total costs estimated to be more than $1 trillion. The odds of having a diagnosis of AD when over 85 years of age exceed 1:3 (15). One in six people over 80 years in the UK have dementia (16). Estimates for the prevalence of AD in USA indicate that more than 5 million individuals who are 65 years or older currently suffer from AD (1, 15). About 200,000 subjects have been diagnosed with the early-onset familial
AD form and health care costs for this disease are about $200 billion per year (1). It is clear that AD is fast becoming a major health challenge in the USA and around the globe that will financially drain public health budgets and care giver services.

NEUROPATHOLOGICAL CHARACTERISTICS OF THE AD BRAIN

The AD brain is characterized by several neuropathological features of which two seminal hallmarks (Fig. 1) arise from proteostasis of the ongoing neurodegenerative processes and are essential for a definitive diagnosis of the disease at post mortem (17). One of the hallmark proteins is made up of fibrils in the form of extracellular, insoluble plaques and consists primarily of amyloid-beta (Aβ) (18). The peptide deposits in variable sizes depend upon the secretase enzymes (α-, β- and Y-secretases) that cleave it from the longer amyloid precursor protein (APP). Initial reports suggested fibrillar Aβ to be neurotoxic (19) as it has been shown to kill all types of cells by apoptosis induction (20). However, there are two known insoluble fibrillar Aβ amyloid peptides comprised of Aβ40 and Aβ42 amino-acid residues as well as their different which exhibit distinct physiological states within the human brain. There is a general consensus among scientists that the larger (Aβ42) peptide is the neurotoxic form as the ageing brain of cognitive intact individuals also displays Aβ plaques. However, in the cognitively intact brain they are fewer in number and usually of the diffuse Aβ40 type that appears not to bear any, as yet known, pathological significance in the elderly who age successfully. In monomeric, dimeric and the multimeric forms of Aβ (21). The relative neurotoxicity of these isoforms remains unclear. It is not clear as to which one of these is more neurotoxic (22).

More recently, the fibrillary forms of the Aβ40/42 peptides released in the AD brain are also recognized as "defensin" or innate immune defense molecules that act to protect the host against infection (23). For example, both of the aforementioned amyloidogenic peptides can
bind to bacterial membranes and in that way lyse bacterial cells. Although Aβ is acting as an antimicrobial peptide (AMP), it may be a part of the brain’s ancient/modern innate immune defense mechanism. AMPs are potent, broad-spectrum, pore-forming agents against targeting Gram-negative and Gram-positive bacteria, enveloped viruses and protozoans (23), thereby supporting the hypothesis that AD has an infectious origin.

Furthermore, the senile plaques (Aβ42) are recognized as triggers that stimulate activation of microglial cells and initiate local immune responses (24). Activated microglia are the most important contributors of inflammation in the central nervous system (CNS) (25). They secrete a number of proinflammatory cytokines (24-26) and recognize pattern associated molecular patterns (PAMPs) on bacteria and their cellular debris (27-30) to deal with in response to CNS infection.

The other pathological characteristic of AD is an accumulation of intracellular hyperphosphorylated tau and heat shock proteins constituting the neurofibrillary tangles (NFTs). Hyperphosphorylated tau protein alters the polymerization and stability of microtubules compromising their function (31). NFTs in AD reflect the severity of disease; however, the significance of pathogen-host interaction to the occurrence of NFTs in the AD brain is poorly understood. Current genetic evidence is pointing to aberrant innate immune responses (32, 33) and cholesterol lipid genes (see 34) having greater significance in AD pathogenesis. A dysfunctional immune system and predisposition to hyperlipidaemia also support the role of reduced blood flow due to the vascular lesions and inflammation, Aβ deposition and microorganisms in AD.

In advanced AD pathology, synaptic dysfunction is another structural defect associated with a decline in memory (35-37). Although a circular argument, malnutrition plays a role in the gradual loss of synapses and fewer teeth during life is a known risk factor for AD (38).
Neurons are capable of responding to injury by expressing multiple neurotransmitters. In AD, selective loss of cholinergic neurons in the basal forebrain (39) also correlates with the loss of cognitive function (18, 35).

THE AMYLOID CASCADE HYPOTHESIS

Several hypotheses have been launched for advanced regarding the development of AD. The amyloid cascade hypothesis serves as a model particularly for the familial form of AD (40), which is a disease caused by mutations involving the amyloid-β protein precursor, located on chromosome 21 and presenilin 1 and 2 on chromosomes 14 and 1 respectively that enhance the APP gene processing towards Aβ deposition (41, 42). The model, which was first proposed by Glenner and Wong (43), maintains that the neurodegenerative disease is due to an imbalance between the generation and clearance of Aβ. Genome wide association studies (GWAS) highlighted the complement receptor 1 (CR1) gene playing a role in AD pathogenesis (44). One recognized role of CR1, a membrane bound regulatory protein, is its ability to bind C3b opsonins (Fig. 2). It is abundantly expressed especially on erythrocyte membranes and as such participates in immune complex clearance by transporting waste to the liver and the spleen. As the CR1 gene is a risk factor for LOAD, this suggests loss of function as a possibility for the defective clearance of Aβ in the brain. Other tentative explanations suggest variation in CR1 protein isoforms (longer and shorter forms) (45), whereby the longer form is somehow negatively less involved in the disease process via its ability to bind more C3b and facilitate more effective clearance of Aβ in the brain (46). This is a process that inevitably fails favouring disease expression with more Aβ proteostasis buildup and complement pathway activation. The amyloid hypothesis has been modified several times, particularly due to the finding that soluble oligomers of Aβ may contribute to
early preclinical stages of the disease that initiate the cascade leading to synaptic dysfunction, atrophy and neuronal loss (47).

THE INFLAMMATORY HYPOTHESIS

The intrinsic model

Currently there are two models of the inflammatory hypothesis of AD, an intrinsic and an extrinsic. The intrinsic inflammation model accounts for the intact “blood-brain barrier” (BBB) restricting entry of neurotoxic immune molecules and systemic lymphocytes to the brain. As a consequence, the brain glial cells are able to generate a local and complete innate immune system when challenged by foreign agents (26, 48-50). Historically, neuroinflammation has largely been viewed as being a downstream consequence of the amyloid hypothesis, whereby the presence of amyloidogenic peptides result in the activation of microglia initiating pro-inflammatory cascades and the release of potentially neurotoxic substances resulting in degenerative changes in neurons. GWAS now implicates innate immune genes (44, 51) as being a risk factor and supports a primary role for the inflammatory elements of AD pathology via inappropriate activation of the complement system (52-54) in association with Aβ plaques and NFTs (55).

The extrinsic model

The extrinsic model accounts for communication of the glial cells with the immune challenges presented via the blood vascular system using the circumventricular organs and the choroid plexus that are devoid of the BBB (56). The cells from this region of the brain are fully equipped with the CD14 receptor and the toll-like receptor 4 (TLR 4) to recognise the peripheral blood circulation (27, 28). Hence, elements of systemic infections such as those
originating from Gram-negative, highly virulent oral pathogens, bronchopneumonia and urinary tract infections (3, 4, 7, 57, 58) reach all organs including the CNS. The consequences products entering the bloodstream trigger the are that the innate immune responses of hosts' pattern recognition receptors (PRR) and TLRs via pattern recognition receptors (PRR) and infectious threat by secreting to the threat of infection by secreting immune mediators agents. Increased risk of dementia in the elderly following multiple infectious episodes has been reported. It is reported that multiple episodes of infections in the elderly likely end up being diagnosed with dementia (4). In addition, systemic infections appear to contribute towards delirium in some clinically diagnosed AD patients and such episodes can exacerbate a premorbid cognitive status (3). Holmes et al. proposed that since cytokines are primary mediators released by the host to defend against infection, such secondary stimuli (IL-1β and TNF-α) may mediate their effect on the brain and indirectly contribute to cognitive decline (3, 57).

NON-ORAL BACTERIA RELATED TO AD

Honjo et al. (59) using Bradford Hill’s criteria for assessing the relationship between bacteria and disease found Chlamyphila pneumoniae to be a likely infectious agent related to the pathogenesis of AD. Maheshwari and Eslick (60) reported a strong correlation between C. pneumoniae and AD, and according to Shima et al. (61) C. pneumoniae is currently the most plausible of all infectious agents proposed to be involved in AD. Lim et al. (62) suggested that the pro- and chronic inflammatory states in AD pathogenesis may in part be due to C. pneumoniae infection of monocytes. C. pneumoniae antibodies from typical intracellular and atypical C. pneumoniae antigens have been identified both from typical intracellular and of the brains from AD patients (63). Amyloid deposit and NFTs were detected in the same
regions in apposition to one another suggesting that *C. pneumoniae* infection is involved in
the development of AD pathology.

Using various techniques Balin et al. (9) found *C. pneumoniae* in 80-90% of LOAD brain
tissue specimens. *C. pneumoniae* infection was correlated with the *APOE*ɛ4 allele expression.
The same researchers subsequently demonstrated that astroglia, microglia, neurons,
endothelial cells and monocytes in the LOAD brain are permissive to this bacterium. The
mechanisms of pathogenesis differ between actively- and persistently-infecting chlamydiae
and it is in the persistent state that these organisms cause chronic disease (64, 65). *C.
pneumoniae* was cultured from two AD brain samples after one or two passages in HEp-2
cells (66). Interestingly, the study indicated that brain isolates were more related to respiratory
than to vascular/atheroma strains of *C. pneumoniae*. This suggested that *C. pneumoniae*
infection of the brain was secondary to bronchopneumonia and at the end stages of LOAD.

It has been suggested that the phages phiCPAR39 and phiCPG1, associated with *C.
pneumoniae*, may enter mitochondria of the bacterial host and work as slow viruses initiating
AD (67). These authors hypothesized that mitochondrial recruitment by *C. pneumoniae*
phages may be the primary initiating event in the pathogenesis of neurodegenerative
disorders.

In a meta-analysis based on 25 relevant, primarily case-control studies Maheshwari and Eslick
(60) found a statistically significant association between AD and detectable evidence of
infection caused by *C. pneumoniae* or spirochetes. They reported over a ten-fold increased
occurrence of AD when there was evidence of spirochetal infection (OR: 10.61; 95% CI:
3.38-33.29) and over a four-fold increased occurrence of AD with a conservative risk estimate
(OR: 4.45; 95% CI: 2.33-8.52). There was a five-fold increase in occurrence of AD with *C.
pneumoniae* infection (OR: 5.66; 95% CI: 1.83-17.51). Accordingly, a strongly positive
association between bacterial infection and AD was shown for both types of bacteria, but it was strongest for spirochetes.

It is generally accepted that the syphilis spirochete *Treponema pallidum* can cause chronic neuropsychiatric disorders including dementia as well as other neurodegenerative disorders (11). *T. pallidum* causes brain atrophy and Aβ deposition in the atrophic form of general paresis (68, 69) and is a strong indication for involvement of spirochetes in AD pathogenesis. Chronic diseases such as syphilis are frequently associated with deposition of amyloid (68, 69). Actually, amyloid is considered as an integral part component of spirochetes which may contribute to amyloid deposition in AD (70). Syphilis accumulation of spirochetes Spirochete accumulation in the cerebral cortex in the context of syphilis will also lead to formation of senile plaques, NFTs and granulovacular degeneration (71).

Miklossy (68, 69) analyzed data on the ability of spirochetes to induce pathological and biological hallmarks of AD in vitro following Koch’s and Hill’s postulates and demonstrated a plausible causal relationship between neurospirochetosis and AD. The data revealed a statistically significant association between spirochetes and AD (P = 1.5 x 10^-17, OR = 20, 95% CI = 8-60, N = 247). When mammalian cells were exposed to spirochetes, the pathological and biological hallmarks of AD were reproduced in vitro (68, 69). Miklossy (72) also found that historical observations paved the way for drawing conclusions such as chronic spirochetal infections can cause dementia and reproduce the neuropathological hallmarks of AD (72). According to Miklossy (72), these observations represent further evidence in support of a causal relationship between various spirochetal infections and AD.

Another spirochete also implicated in AD is, *Borrelia burgdorferi*, has also been implicated in AD. This is the causative agent of Lyme disease which is transfected to humans via
There are great similarities in the clinical and syphilis and Lyme disease (72, 73). The occurrence of *B. burgdorferi* in the brains of AD patients was first reported by MacDonald and Miranda (74) and was confirmed later by MacDonald (75, 76), Riviére et al. (5) and Miklossy et al. (77). Interestingly, Bu et al. (78) found that the infectious burden consisting of *B. burgdorferi, C. pneumoniae, Helicobacter pylori, cytomegalovirus*, and *Herpes simplex-1 (HSV-1)* is associated with Gutacker et al. (79) and Pappolla et al. (80) found no evidence for an association between *B. burgdorferi* and AD. Among other bacterial species, *H. pylori* alone (monoinfection) has been found to be related to AD (59). These authors suggested that AD pathology can be initiated and exacerbated by some microorganisms with inflammatory and oxidative responses which may affect the brain continuously and gradually over time. However, the *H. pylori* status did not depend on was not associated with AD in a study from Japan, probably due to the high prevalence of the organism in controls (81). This was refuted by Kountouras et al. (82) who had previously found that successful eradication of *H. pylori* infection was associated with significantly lower mortality risk in AD patients [HR (95% CI)=0.287 (0.114-0.725), p=0.008] (83).

**ORAL BACTERIA RELATED TO AD**

The oral cavity harbours an impressive range of bacterial phylotypes (84). Molecular identification methods have detected close to 900 different predominant bacterial species of which 35% cannot yet be cultured (85). The oral microbiome profiles appear to be individualized (86), meaning that bacterial microbiomes can vary both qualitatively and quantitatively between individuals, although there are also significant overlaps. Each individual can harbour up to 200 different bacterial taxa in their mouth and there is a
variation in the microbiota in different oral sites (84, 87). Furthermore, the composition of the oral microbiota irrespective of being indigenous or pathogenic in the oral cavity keeps changing in view of major oral diseases (caries, gingivitis, aggressive and chronic periodontitis, periodontal-endodontic lesions, peri-implantitis and mucositis) (88-94).

Particularly plaque-induced oral diseases such as periodontitis are associated with a change in the oral microbiota. There is a predominance of anaerobic bacteria in the oral cavity. Many of the major periodontal microorganisms are anaerobic, e.g., *Porphyromonas gingivalis*, *Treponema denticola* and *Tannerella forsythia*. The abundance of anaerobes tend to increase with the development of plaque-induced oral diseases.

**Periodontal bacterial pathogens are related to AD**

Major pathogens of chronic periodontitis such as *P. gingivalis, T. forsythia*; and *T. denticola* are implicated in the development of several inflammatory diseases at remote organ sites. Except for *T. forsythia*, all the above three of the above-named organisms of which *T. denticola* represents a spirochete, have been found in the AD brain (5, 8). Spirochetes are strongly neurotropic. They can spread along nerve fibers and via lymphatics (67, 68) and have been detected in the trigeminal nerve and trigeminal ganglia (95). Spirochetes and their antigens as well as DNA have been found associated with AD and are strongly implicated as the causative agents leading to dementia (68, 69). In 14 studies spirochetes were detected in AD by different authors in different laboratories and countries by means of different techniques (for a review see Miklossy (68, 69). Riviere et al. (5) demonstrated the presence of seven different oral *Treponema* species in 14 out of 16 AD brain specimens (Fig. 3).

Spirochetes were even cultivated from the brains of AD patients indicating that they were viable in the brain (67, 68, 77). Miklossy suggested a co-infection by several spirochetes in...
AD including the oral varieties (T. socranskii, T. pectinovorum, T. denticola, T. medium, T. amylovorum and T. maltophilum) as demonstrated by Riviere et al. (5). Spirochetes reproduced the biological and pathological hallmarks of AD after exposure of mammalian neuronal and glial cells in organotypic cultures (68, 69).

It has been demonstrated that LPS from periodontal bacteria can access the AD brain during life as-while detection in corresponding controls, with equivalent or longer postmortem interval was absent (8). This study supports the literature on elevated antibodies to periodontal disease-associated bacteria such as P. gingivalis, being found in AD patients (7). Furthermore, in 2,355 people 60 years and over, the third NHANES study found associations between periodontitis and cognitive impairment and between measures of immunoglobulin to P. gingivalis and cognitive test performance (96, 97) used cohort methodology analyzing serum levels of antibodies to periodontal disease. All participants were cognitively intact at baseline. Those who went on to develop AD had higher levels of serum antibodies to periodontal pathogens at baseline. This study suggested a temporal periodontal disease came before AD.

Other important periodontal pathogens related to AD are Fusobacterium nucleatum and Prevotella intermedia. In the NHANES study antibody levels to these organisms were significantly increased (α = 0.05) at baseline serum in patients with AD compared to controls (97). The results were significant after controlling for baseline age, Mini-Mental State Examination score, and allele APOEε4 status. Noble et al. (98) found that a high anti-Actinomyces naeslundii titer (> 640 ng/ml, present in 10% of the subjects) was associated with increased risk of AD (HR=2.0, 95% CI: 1.1-3.8). This association was stronger after adjusting for other significant titters (HR=3.1, 95%CI: 1.5-6.4) and confirmed that periodontal pathogens can be associated with AD.
Possible consequences to the brain of carrying oral bacterial pathogens

The fact that inflammation is sustained in the AD brain suggests that local immunogenic hallmark proteins and/or peripheral infections are key perpetrators. This is supported by reports highlighting microorganisms and their toxic products as well as DNA in brain tissue of AD patients and experimental animals (see later below). Bacteria activate pathways that include the integrin receptor CR3 (CD11b/CD18) and TLR signalling (99) and the complement cascade (100). The NF-κB signalling pathway for cyto/chemokine release (TNF-α, IL-8) (101) produces free radicals, nitric oxide triggers and apoptosis (102). The oral cavity, lungs and gastrointestinal and urinary tracts are plausible sources of brain microorganisms. The likely passage of the microorganisms of interest from their original sites to the brain is described below.

Infections with spirochetes can cause cerebral hypoperfusion (103), cerebrovascular lesions and a severely disturbed capillary network (68, 69). Chronic spirochetal infection can also induce slowly progressive dementia, cortical atrophy, chronic inflammation and Aβ deposition, which cannot be distinguished indistinguishable from that occurring in AD brains (for reviews see 68, 69, 72). Furthermore, cultured neuronal cells exposed to spirochetes produce Aβ (104). Spirochetes are also able to form plaque-, tangle- and curly fiber-like lesions (72, 105). They induce a latent and slowly progressive infection by evading host defenses. This promotes their survival and proliferation in the brain by blocking the complement cascade. Spirochetes may even survive and proliferate in hosts that are immune-competent. By evading host’s defenses, spirochetes induce a latent and slowly progressive infection to promote their survival and proliferation in the brain and by blocking the complement cascade spirochetes may survive and proliferate even in hosts that are immune-competent. Interestingly, the remarkable ability of T. pallidum to evade clearance from the
immune system has earned it the designation “stealth pathogen” (106). Also an The activated complement cascade can be seen following spirochete infections (11) which may be used as a non-specific marker of CNS inflammation. Spirochete-host interactions initiate and sustain chronic inflammation triggering various immune responses that activate and end up with various immune responses activating the innate and adaptive immune system, free radicals production, apoptosis and amyloid deposition typically seen in AD brains (107).

*P. gingivalis* has been designated as one of the “keystone” periodontal pathogens because it is able to establish and maintain the periodontal disease-associated “inflammophillic” microbiota (108). It is able to perform this task as it possesses an awesome variety of virulence factors, recently reviewed by Singhrao et al. (109), to evade the host immune defenses, thus serving two major functions: initially for survival of *P. gingivalis* itself via a sustainable inflammatory milieu and then to sustainment of nutritional sources by eliminating microbial competitors needs and to stamp out competition (108).

The *P. gingivalis* endotoxin LPS demonstrates differences in the number of phosphate groups together with both the amount of lipid A fatty acids and their specific position. The presence of multiple lipid A structures makes it more difficult for the innate host responses to recognize the molecule thereby aiding the virulence of *P. gingivalis* (110). The consequences of finding *P. gingivalis* LPS in the host’s body, e.g. the brain (8), are include priming of cells for differential activation of the TLR-mediated NF-κB signalling pathway (111) leading to cytokine liberation, complement activation and maintenance of intracerebral inflammation.

*P. gingivalis* evades circulating phagocytes by adhering to erythrocytes (112). An active invasion of *P. gingivalis* and infection-induced complement activation with bystander neural injury was detected in the brains of ApoE<sup>−/−</sup> mice (113). This supported previous notions that bacterial infections can contribute to the development of AD pathology via mechanisms...
involving acute phase proteins such as cytokines and the complement cascade where neurons would be attacked.

ORAL VIRUS RELATED TO AD

Herpes simplex virus (HSV) is present in more than 70% of the population after 50 years age (114-116). It persists latently in the peripheral nervous system and is periodically reactivated. Characteristically, HSV-1 has been designated as the enemy within (10). Herpes viruses, including Epstein-Barr virus and cytomegalo-virus, are found in high copy counts in aggressive periodontitis, and may interact synergistically with periodontopathic bacteria in the pathogenesis of this disease (117). Periodontal infections activated by Herpes virus herpes may impair local host defenses and thus increase the aggressiveness of resident periodontopathic bacteria. The bacteria, in turn, may augment the virulence of the herpes viruses.

High proportions of viral-associated proteins in amyloid-containing plaques and/or NFTs corroborate with the involvement of HSV-1 in AD pathology (118). This supports a study by Notably, De Chiara et al. (119) who found reported an association between Aβ accumulation in the brain and HSV infection. Itzhaki et al. (120) suggested that not only does HSV-1 produce the main components of amyloid plaques and NFTs (i.e. Aβ and hyperphosphorylated tau), but it also interferes with the autophagic events that prevent degradation of these proteins and eventually leading to their accumulation in the AD brain. Further, in vitro and in vivo investigations using mouse in murine models following HSV-1 demonstrated Aβ accumulation (121).

A number of scientists have suggested that there is imbalance between production and clearance of β-amyloid in the brain, a thought premise first proposed by Wisniewski et al.
on the discovery of soluble species of this protein and later confirmed by Zlokovic et al. (123)
(123) to be the case. Thus it is now widely accepted that defective clearance of this protein
brains that leads to its accumulation in the form of insoluble Aβ40/42 plaques.
and cytomegalovirus have been detected in the brains of older adults with and without AD
(124-126), HSV-1 viral DNA is present in a higher proportion of AD patients (127). It is
particularly seen in the temporal and frontal cortices which are the brain regions that are most
damaged in AD (128, 129). The relevance of this association is still under investigation;
however a plausible role for the HSV-1 viral DNA could be in association with the plaque
maturation process. Jamieson et al. (127) found that the virus was absent from the brains of
most young people, probably because it enters the brain during old age either when the
senescence (130) or the virus itself is initially responsible for weakening the host’s immune
defenses first. This latter explanation is likely and is supported by us and others (131).
HSV-1 is a strong risk factor for AD in the brains of those with the APOE ε4 allele (125, 132).
This virus is not only a dormant passenger but can persist in the latent form in neurons or
replicate at a very low level in neuroglia (133). During persistence it may release toxic
products continuously and induce pro-inflammatory cytokines at low levels which become an
additional burden to the host who is already challenged by age, poor diet, exercise
as well as any genetic susceptibilities. Itzaki and Wozniak (10) suggested that stress
or peripheral infection can reactivate the virus periodically from latency in the brain. This
may cause an acute but presumably localized infection, and subsequent damage modulated by
the APOE gene can lead to formation of Aβ plaques and NFTs.
The presence of anti-HSV IgM, a sign of reactivated infection, almost doubled the risk for AD
while anti-HSV IgG did not influence the risk (134). Kobayashi et al. (135) suggested that the
anti-HSV-1 Ig antibody avidity index could be a useful biomarker for early diagnosis of
anamnestic mild cognitive impairment, which is prodromal to AD, as well as for AD sufferers.

Reactivation of HSV seropositivity is highly correlated with incident-AD (136). Letenneur et al. (136) speculated that AD pathology starts many years before frank dementia and recurrent reactivation of HSV can act as a potent stimulus to brain microglia, increasing cytokine levels, and triggering a positive feedback cycle leading to increasing accumulation of neurohistopathological changes. In other words, infection, followed by local CNS inflammatory reaction is the likely primary occurrence stimulus whereas proteostasis is a consequence of the primary event leading to the development of AD.

Hill et al. (137) suggested a role for HSV-1-induced miRNA-146a in the evasion of HSV-1 from the complement system, which is a major first-line host defense mechanism, and the activation of key elements in the arachidonic acid cascade known to contribute to AD-type neuropathological changes.

ORAL YEASTS RELATED TO AD

Oral yeast infection is a secondary opportunistic infection disease of the diseased where particularly involving Candida albicans, but increasingly also non-albicans species, e.g. Candida glabrata are involved. With a growing population of elderly, severe systemic fungal infections have increased dramatically in this age group during the last 30 years (138, 139). Oral yeasts can be found in periodontal pockets, in root canals, on the mucosae and underneath dentures (denture stomatitis) (140-142). Denture stomatitis is prevalent in elderly wearing dentures that are heavily contaminated with yeasts which can be a source of systemic mycosis (Fig. 3). Disseminated mycoses have recently been reported in AD patients (143,
144). Fungal molecules including proteins and polysaccharides [(1,3)-β-glucan] were detected in peripheral blood serum, and fungal proteins and DNA were demonstrated by PCR in brain tissue of AD patients. Also, chitin-like fungal structures have also been found in the AD brain (145) and chitinase activity has been proposed as a powerful biomarker of AD (146).

Immunohistochemical analyses revealed, albeit in a few cells, in AD brains containing cytoplasmic material in a small number of cell cells were targeted by antibodies with immunoreactivity to that immunoreacted with antibodies raised against some yeast cells (147). These findings were consistent with the idea that neurons can be infected by fungi. Interestingly, antifungal treatment reversed the clinical symptoms of some AD patients (148, 149).

**Blood stream dissemination**

The most likely pathway of dissemination for oral microorganisms to the brain is through the blood stream (150). Dental treatment procedures as well as brushing, flossing, chewing and use of tooth picks in a patient with periodontitis will release a bacteremia (151). This can occur several times during the day and has been estimated to last for up to 3 hours for oral bacteria (152). The bacteremia is usually taken care of by immune cells of the body. However, in people with reduced immune defense, e.g. older individuals, bacteria may settle down within crevices of the oral cavity and vascular channels (150).

**The blood-brain barrier**

An intact blood-brain barrier (BBB) prevents microorganisms in the blood from accessing the brain. However, aging favors overgrowth of oral microorganisms, particularly anaerobic bacteria and facultative yeasts that established earlier in life and provoked pro-inflammatory
responses that weakened the BBB (16). Actually, magnetic resonance imaging (MRI) confirmed loss of BBB integrity in a mouse model of disseminated candidosis (153). Loss of integrity allows microorganisms to spread through the blood stream and quietly contribute in the pathogenesis of AD. During immunosenescence, the innate immune system gradually takes over for the acquired immune system. This contributes to a rise in circulating proinflammatory cytokines such as TNF-α (16). Indeed, proinflammatory mediators can cross the BBB (3, 7, 154). APOE ɛ4, TNF-α and perhaps Ephrin Type-A Receptor 1 (EphA1) may influence BBB integrity and thus be important for penetration of bacteria, LPS and other toxic bacterial products as well as yeasts into the brains of AD patients (16). APOE ɛ4 affects the integrity of the BBB by activating the cyclophilin A matrix metalloproteinase MM-9 pathway (155).

It is also plausible to suggest that the permeability of the BBB increases with age and thus promotes AD pathogenesis making the brain accessible to microorganisms. Mice with a mutation in the amyloid precursor protein gene which is related to early-onset AD in man, showed increased permeability of the BBB and increased formation of senile plaque compared to control mice (156). The changes increased with age.

Circumventricular organs and perivascular spaces

Circumventricular organs (permit polypeptide hypothalamic hormones to leave the brain without disrupting the BBB) are not dependent on the BBB (56) and may act as another entry portal to the brain for bacteria (157). Poole et al. (8) postulated that bacteria and their products may also directly access the brain via the systemic circulation through the perivascular spaces.
The olfactory hypothesis

The “olfactory hypothesis” suggests the olfactory tract as a potential route for pathogenic bacteria to enter the brain and thereby trigger the production of Aβ and NFTs (158). The olfactory and trigeminal nerves are known to be used by periodontal pathogens to bypass the BBB for direct passage to the CNS (5, 150, 159, 160). Identification of oral treponemes in the trigeminal ganglia supports such a route of dissemination (5). Further, spirochetes may also spread along the fila olfactoria and tractus olfactorius (68, 69).

Olfactory unsheathing cells (OECs) engulf bacteria and migrate towards TNF-α released by activated astrocytes (161). Therefore, OECs could be a vehicle for transporting live bacteria to the brain (i.e., Trojan horse). The olfactory bulb was the first area where NFTs and Aβ deposition were detected in the neuropathological trajectory of AD in humans (162) and in mouse models of AD (163).

GENETIC, NUTRITIONAL AND ENVIRONMENTAL FACTORS PROMOTING AD

While early-onset AD is genetically determined, LOAD is thought to result from interaction between genetic and environmental factors (12). Several mutated genes are associated with the familial AD, such as the amyloid beta (Aβ) precursor protein (AβPP) gene and the presenelin-1 (PSEN-1) and PSEN-2 gene (164-166). A major risk factor for LOAD is polymorphism in the APOE4 allele (2). Also cytokine-related genes seem to be involved in the susceptibility to inflammation in both LOAD (167, 168) and periodontitis (169-171). Thus, polymorphisms that increase TNF-α also increase the risk of both AD and periodontitis (172, 173). Lambert et al. (174) found that 20 different loci can increase host susceptibility to AD including polymorphisms in genes associated with interleukin-1 (IL-1) (71, 175-178) and TNFα (71, 172, 179-181). The APOE4 gene which is one of these 20 loci is highly correlated
with AD (182) but it is also a risk factor for infection and increases the expression of inflammatory mediators (11). Recently, genetic overlap between AD, C-reactive protein (CRP) and plasma lipids was demonstrated by using summary statistics from GWAS of over 200,000 individuals (183). There may also be interplay between genetic risk and environmental risk factors such as toxins and or bacterial, viral and fungal pathogens in LOAD reflecting its complex and multifactorial etiology (1).

Diet with its content of essential B-vitamins, phospholipids and other micronutrients are important for forming new nerve synapses (184). Nutritional deficiencies are common both in elderly and in dementia subjects as briefly discussed by Singhrao et al. (150).

ASSOCIATION BETWEEN CHRONIC PERIODONTAL DISEASE AND AD

There is increasing evidence for an association between chronic periodontitis and LOAD (185). Cross-sectional and longitudinal studies have demonstrated that gingival bleeding, loss of periodontal attachment, periodontal probing depth, alveolar bone loss and antibodies to periodontal pathogens are significantly associated with lower cognitive function and decline after adjustment for co-variates (for a review see (12)). Acute phase proteins, including cytokines are possible indirect links between periodontal pathogens and/or their virulence factors (12, 13). Elderly often show neglect of oral hygiene (Figs. 3-5) which can stimulate recurrent chronic oral infection (150). This again promotes inflammation which can lead to confusion and dementia (3, 4, 154). In 152 subjects 50-70 years of age who were followed for 20 years, greater levels of periodontal inflammation correlated with lower cognitive levels (186). Furthermore, gingival bleeding and loss of periodontal attachment were associated with cognitive impairment in a cohort of 5,138 people aged 20-59 years (187). In 144 nuns, those with encoding APOEε4 and who had fewer teeth experienced more rapid
decline than those with neither or either of these risk factors (188). Clinical and 
epidemiological studies showed that loss of teeth is associated with poor memory (6, 96, 187, 
189). In another study with of 597 community dwelling men followed for 32 years, tooth loss, 
increasing periodontal pockets depths and progression of alveolar bone loss were associated 
with impaired cognition particularly in those over 45 years of age (190). Recently, de Souza 
Rolim et al. (191) found that periodontal infections were more frequent in patients with mild 
AD than in healthy subjects. Another interesting feature related to the pathogenesis of AD is 
the low level of infection by “commensals on the loose” (16). These “immuno-tolerated” 
bacteria may silently multiply in sites outside of their primary niche and an ongoing illness 
at their secondary location may have significant deleterious effects upon the health of the 
elderly or demented host with an existing immunocompromised status.

PUTATIVE TREATMENT AND PROPHYLAXIS OF AD

There is no effective treatment or prophylaxis yet for AD, but several approaches have been 
proposed. Efforts in this respect are important. If we could delay onset of dementia by only 2 
years we might lower the prevalence of AD by more than 22 million cases over the next 40 
years (14). Indeed, delaying the disease process is a better option as the Notably, Notably, the 
of the APOE4 allele in the very old (90+) age group, appears to confer protection (192), 
having bypassed a period of being at risk around 85+ years of age.

If periodontal disease is implicated in AD, periodontitis prophylaxis should be feasible could 
be of help. It would be interesting to see if this has any effect on the initiation and aggravation 
of AD but an observation period of decennia is probably needed.

In a study of subjects with mild to moderate AD, a 3-month course of doxycycline and 
rifampicin reduced cognitive deterioration in-during a 6 months’ follow-up interval
study in subjects with mild to moderate AD (193). It was concluded that use of antibacterial
the treatment of C. pneumoniae but had a beneficial effect on cognitive decline in AD (193).
This might be related to prevention or attenuation of a number of peripheral infections or
dampening down the proinflammatory cytokine response. Minocycline was found
early, pre-plaque neuroinflammation and inhibit the APP cleaving enzyme 1 (BACE-1) in a
transgenic model of Alzheimer's disease-like amyloid pathology (194). It was suggested that
interfering with inflammation could be a useful therapeutic approach in early, pre-plaque
stages of AD-like amyloid pathology.

Anti-inflammatory drugs given for at least 2 years before the onset of dementia delayed the
disease process (194, 195, 196, 197). It may also be beneficial to combine anti-inflammatory
antibacterials (193). Examination of several available Non-steroidal Anti-Inflammatory Drugs
(NSAIDs) showed that only a few of them had any useful Aβ-modifying or other activity of
therapeutic use in LOAD (for a review see (1)).

Itzhaki and Wozniak (10, 198) suggested that antiviral therapy and perhaps vaccination
against HSV-1 in early life could be useful. If HSV-1 is implicated in AD, vaccination could
prevent the excessive accumulation of Aβ in the brain. Vaccination with mixed HSV
glycoproteins prior to HSV infection protected against viral latency in mouse brains (198, 199).
Also Mori (199, 200) maintained that antiviral approaches including chemotherapy and
vaccination are promising for prevention and treatment of AD and remain to be validated.
Furthermore, Carter (118) suggested that vaccination or antiviral agents and immune
suppressants may be considered as therapeutic options before or in during the early stages of
AD. Interestingly, exposure of HSV-1-infected cell cultures to intravenous immunoglobulin
acting via anti-β-amyloid antibodies reduced the accumulation of Aβ and
phosphorylated tau (200, 201).
Angiotensin-converting enzyme (ACE) from *Stigmatella aurantiaca* may cleave the Aβ peptide similar to human ACE and may be used as a novel form of treatment against AD ([201202](#)). Furthermore, Chiarini et al. ([202203](#)) maintained that calcilytics could halt AD progression and preserve the patients' cortical neurons, cognitive abilities, and eventually life if given at minimal cognitive impairment or at earlier stages. Studies from using *Caenorhabditis elegans* mice suggested the use of tau aggregation inhibitors as potential drugs for the treatment of AD and other tauopathies ([203204](#)).

Resveratrol is a polyphenol present in red wine. Its capability of directly interfering with the toxic β-amyloid protein aggregation in AD has recently been shown ([204205](#)). Resveratrol was found to reduce Aβ-induced toxicity in a *Caenorhabditis elegans* model of AD by targeting specific proteins involved in proteostasis and thereby reducing the amount of aggregated Aβ ([205206](#)). This is in concert with our previous finding that the effect of a drinking pattern of 2–7 times per week reduced the risk of myocardial infarction among men who had a history of tooth extractions due to periodontal/dental infection ([206207](#)).

Potent inhibitors of Aβ oligomer formation or Aβ-induced cell toxicity have proven to be attractive means for therapeutic intervention of AD. Song et al. ([207208](#)) found that the anti-Alzheimer effects of centipedegrass, which contains several C-glycosyl flavone constituents, occurred through inhibition of neuronal cell death by intervening with oligomeric Aβ formation and reducing beta-site amyloid precursor protein cleaving enzyme 1 (BACE1) activity. The authors suggested that Maysin, a major flavonoid of corn silk, in centipedegrass could be an excellent therapeutic candidate for the prevention of AD.

Active immunization against important domains of Alzheimer tau eliminated tau aggregation and neurofibrillary pathology ([208209](#)). The AD type of tau hyperphosphorylation was abolished in transgenic mice by vaccination across a wide range of AD phospho-epitopes.
Kontsekova et al. (208209) demonstrated that active immunization of rats with a tau peptide encompassing the epitope revealed by monoclonal antibody DC8E8 led to elimination of all major hallmarks of neurofibrillary pathology involving a 95% reduction in the AD-type hyperphosphorylation of tau.

CONCLUSIONS

LOAD which is the predominant form of AD, does not seem to have a single cause. On the contrary, a multitude of factors may be involved and they may act in concert. Among others, both genetic and environmental factors may be involved. Even among cooperation, action may occur since the brain can hardly differentiate between different microbial insults which collectively contribute capacity for enhancing all end up in events causing AD, oral microorganisms may play a role, particularly anaerobic bacteria such as treponemes, P. gingivalis, Prevotella spp., Fusobacterium and Actinomyces, but also facultative anaerobic Candida species. It is important to recognize that infection can occur decades before the manifestation of dementia. The most convincing evidence for a causal relationship between oral bacteria and AD is that noted for spirochetes which are both neurotropic and motile. They also fulfill Koch’s and Hill’s postulate for a causal relationship.

It is likely that oral infection can be a risk factor for Alzheimer’s disease but it is not the only one. Experiments in humans in vivo may require long exposure times to disclose key events and mechanisms of AD. There is, as yet, no cure for AD despite concerted efforts and investment by industry and this is not without concerted efforts from investment by industry but because drug discovery in dementia is hugely challenging. Prevention of AD through
long-term use of antibiotics may be impractical and could select for resistant bacteria. This is worrying as the prevalence of AD and the public expenses related to its management are expected to increase greatly in the next decade.

in AD, 

this oral disease, periodontitis is modifiable. However, improving oral hygiene and treating in the AD patient can be challenging since patients are often uncooperative. There is also for training care-givers to assist with oral care in such patients.

Vaccination against key organisms and important domains of AD has had some beneficial effect. Also several agents interfering directly with the pathogenesis of AD have been tested. In order to find a cure, there is a need for clinical diagnostic information and knowledge of the causal agents for AD. AD causative agents so that specific treatment options targeting these organisms, against these organisms, can be developed. As for diagnostic biomarkers, increased antibody levels to specific oral pathogens in particular to P. gingivalis may be used as a preventive monitoring tool years before clinical manifestation of AD. This is important because treatment will probably have to start early.
