ABSTRACT

We present accurate models of the gravitational potential produced by a radially exponential disc mass distribution. The models are produced by combining three separate Miyamoto–Nagai discs. Such models have been used previously to model the disc of the Milky Way, but here we extend this framework to allow its application to discs of any mass, scalelength, and a wide range of thickness from infinitely thin to near spherical (ellipticities from 0 to 0.9). The models have the advantage of simplicity of implementation, and we expect faster run speeds over a double exponential disc treatment. The potentials are fully analytical, and differentiable at all points. The mass distribution of our models deviates from the radial mass distribution of a pure exponential disc by <0.4 per cent out to 4 disc scalelengths, and <1.9 per cent out to 10 disc scalelengths. We tabulate fitting parameters which facilitate construction of exponential discs for any scalelength, and a wide range of disc thickness (a user-friendly, web-based interface is also available). Our recipe is well suited for numerical modelling of the tidal effects of a giant disc galaxy on star clusters or dwarf galaxies. We consider three worked examples; the Milky Way thin and thick disc, and a discy dwarf galaxy.

Key words: methods: numerical – galaxies: kinematics and dynamics.

1 INTRODUCTION

The mass distribution of the stellar disc of most galaxies is well represented by a radially exponential profile (Freeman 1970). It is advantageous to be able to accurately model the potential field, accelerations, or tides that arise from a mass distribution with an exponential profile. A radially exponential disc profile has the following form:

$$\Sigma(R) = \Sigma_0 \exp(-R/R_d),$$  \hspace{1cm} (1)

where $\Sigma$ is the surface density, $\Sigma_0$ is central surface density, $R$ is radius within the disc, and $R_d$ is the disc scalelength.

Radially exponential discs may have different vertical density distributions. For galaxy discs, a commonly used form for the vertical density distribution is a sech$^n$ form:

$$\rho(R, z) = \rho_0 \exp(-R/R_d) \sech^n(-|z|/z_0),$$  \hspace{1cm} (2)

where $z_0$ is the scaleheight, and $n$ is typically $\sim$1–3.

Another form of radially exponential disc, the ‘double exponential’, has an exponentially decaying vertical distribution:

$$\rho(R, z) = \rho_0 \exp(-R/R_d) \exp(-|z|/h_z),$$  \hspace{1cm} (3)

where $h_z$ is the exponential disc scaleheight. In fact, the double exponential is a special case of equation (2) when $n \rightarrow \infty$. To calculate the potential from a double exponential disc, it is necessary to perform the following integral (Binney & Tremaine 1987):

$$\Phi(R, z) = -\frac{4 G \Sigma_0}{R_d} \int_{-\infty}^{\infty} dz' \exp(-z'/h_z) \times \int_0^\infty dR' \sin^{-1} \left( \frac{2R'}{A_+ + A_-} \right) R' K_0(R'/R_d),$$  \hspace{1cm} (4)

where $A_+ = \sqrt{z^2 + (R' + R)^2}$, $A_- = \sqrt{z^2 + (R' - R)^2}$ and $K_0$ is the modified Bessel function of the second kind. This integral cannot be performed analytically, and therefore is calculated numerically (e.g. Dehnen & Binney 1998; the galpy package: Bovy 2015), except for in the special case where an infinitely thin exponential disc is assumed.

E-mail: rsmith@astro-udec.cl
Due to these limitations, the potential of disc galaxies has often been modelled using a single Miyamoto–Nagai (MN) disc (e.g. Allen & Santillan 1991; Fellhauer et al. 2006; Fellhauer et al. 2007; Kipper et al. 2010; Smith et al. 2013), as this is analytical, and fully defined and provides continuous derivatives at all points. The potential of a single MN disc is described by the following expression (Miyamoto & Nagai 1975):

\[ \Phi(R, z) = \frac{-G M_{MN}}{\sqrt{R^2 + (a + \sqrt{z^2 + b^2})^2}}, \]

(5)

where \( M_{MN} \) is the total disc mass, \( a \) is the radial scalelength, and \( b \) is the vertical scaleheight. This expression can be trivially differentiated in the \( R \) and \( z \) direction to produce expressions for the acceleration at any location. If \( a = 0 \), the potential of a single MN disc reduces to that of a Plummer distribution (i.e. spherical). For \( b = 0 \), the potential reduces to that of an infinitely thin Kuzmin disc (Kuzmin 1956). Hence by varying the parameters \( a \) and \( b \), mass distributions can be modelled with a range of thicknesses. Additionally, the density of a single MN disc is given by

\[ \rho(R, z) = \frac{M_{MN}b^2}{4\pi R^2} \left[ a R^2 + (a + 3\sqrt{z^2 + b^2})^2 \right]^{-3/2} \cdot \left( z^2 + b^2 \right)^{1/2}. \]

(6)

While most galaxy discs are well represented by a radially exponential profile (see equation 1), a single MN disc is a poor match to a radially exponential disc. Its surface density near the centre is too low, and it attains too high surface density at large radius. We quantify the deviation from a pure exponential disc for the models considered in this paper in the following manner. We calculate the difference in mass found within a radial annuli of a single MN disc and a pure exponential disc, and sum up the absolute of these differences in all annuli out to a chosen radius. In this way, we calculate that the total mass deviation of a single, thin, MN disc from a pure exponential disc is 5.0 per cent at 4 \( R_d \), and 19.9 per cent at 10 \( R_d \).

To improve the match to a radially exponential disc, Flynn, Sommer-Larsen & Christensen (1996) combined three MN (3MN) disc profiles, each with different radial scalelength \( a \), one with negative mass, and all with a single vertical scaleheight \( b \). This model is better at matching a radially exponential disc at large radii, and we calculate the total mass deviation from a thin, radially exponential disc is 9.4 per cent at 4 \( R_d \), and 10.0 per cent at 10 \( R_d \). This 3MN model has since been used extensively for modelling the potential from the disc of the Milky Way (MW; e.g. Hänninen & Flynn 2004; Rodionov & Orlov 2008; Moni Bidin et al. 2015). However, minor alterations to the original parameter values have been used to better match more recent measurements of the MW’s disc scalelength and circular velocity (Gardner & Flynn 2010; Jilková et al. 2012; Moyano Loyola et al. 2014). The aim of this study is to extend the utility of the framework introduced by Flynn et al. (1996), a framework which was developed specifically for the recovery of an MW-like radially exponential disc using 3MN potentials. Our extension here allows its general application to discs of any mass, scalelength, and thickness, rather than simply for the singular purpose for which it was initially designed. Our new models also better match the distribution of a radially exponential disc. In Section 2, we derive the new 3MN models, in Section 3 we consider three worked examples, in Section 4 we compare a 3MN model to other well-known disc models, and finally we summarize and conclude in Section 5.

2 NEW 3MN POTENTIALS

From equation (5), a single MN potential has three free parameters; disc mass \( (M_a) \), radial scalelength \( (a) \), and vertical scaleheight \( (b) \). Following Flynn et al. (1996), we choose a single fixed value of \( b \) for all three MN potentials. This substantially reduces the total parameter space we must consider, and ensures our models have a uniform scaleheight. It also enables us to control disc thickness through a single parameter. Thus our 3MN models have a total of seven free parameters; \( M_{MN, 1}, M_{MN, 2}, M_{MN, 3}, a_1, a_2, a_3, b \).

Our aim is to find a combination of these seven parameters that minimizes the mass deviation from a radially exponential disc, out to 4 \( R_d \).1

In order to find a good combination, we used a brute force approach. We fix the value of \( b \), then numerically ran through a grid of values for the other six parameters \( M_{MN, 1}, M_{MN, 2}, M_{MN, 3}, a_1, a_2, a_3 \). For each parameter set, the mass deviation from a pure exponential disc out to 4 and 10 \( R_d \) was quantified numerically. Due to the significant numbers of combinations of parameter values possible, we initially ran with a coarse grid, and then later ran with a finer grid focused on the best matches.

Using this brute-force approach, we find that for an infinitely thin disc \( (b/R_d = 0.0) \), a 3MN model can be found that radially deviates from a radially exponential disc by only 0.4 per cent within 4 \( R_d \), and only 1.9 per cent out to 10 \( R_d \).

2.1 A recipe for different discs: varying disc mass, size and thickness

Our choice of 3MN model has a highly useful property – once a good match to a radially exponential disc of mass \( M_1 \) and scalelength \( R_0 \) has been found, it can be easily scaled to different masses and disc sizes. For example, an equally good match can be found for a disc twice as massive by simply doubling all the MN disc masses \( (M_{MN, 1}, M_{MN, 2}, M_{MN, 3}) \).

Therefore to calculate the best 3MN model with a different thickness, a new six-parameter set must be found. However, if the change in \( b/R_d \) is very small, and smooth, we can expect that each parameter changes in a smooth, and continuous manner. We initially searched for best matches for different disc thicknesses using the brute force approach. However, in practice it was difficult to find a smooth fit-line through these points for which every point on the fit-line provided a good radial match to an exponential. This was also highly time consuming as the brute force approach involves searching through all possible combinations of a broad range of values for each of the six parameters. Thus we changed our approach – instead we use our best solution for an infinitely thin disc, found by the brute-force approach, as a prior, and then use an alternative approach to find the variation of each parameter as a function of \( b/R_d \).

See upper and central panel of Fig. 1. The best solution from the brute force approach is shown by cross symbols. We then shift along the \( b/R_d \) axis in small steps, searching for new solutions that allow a continuous path across the figure, while simultaneously attempting to minimize the differences between the 3MN model and that of an exponential. In practice, this approach is significantly less computationally challenging in comparison to the brute-force approach, as only a small range of possible values for each parameter are permitted in order to form a continuous path. As a result, in

---

1The choice of 4 \( R_d \) is rather arbitrary, however >90 per cent of an exponential disc mass is enclosed within 4 \( R_d \).
a fraction of the computational time required for the brute-force approach to find a single parameter set, hundreds of parameter set solutions are found for a wide range of \( b/R_d \) value. These solutions naturally form a continuous path, allowing a user to choose an arbitrary value of \( b/R_d \) within the permitted range. The solutions are shown by the solid lines in Fig. 1, and cover a range of disc thickness from \( b/R_d = 0.0 \) to 3.0.

The dashed lines in the upper and central panel show a fourth-order fit to the solid lines. This fit produces 3MN models that match a radially exponential disc to <1.0 per cent out to 4 \( R_d \), and <3.3 per cent out to 10 \( R_d \) (dashed black and red line in lower panel, respectively), for the range of disc thickness considered. The fourth-order fit to each parameter has the form:

\[
\text{Parameter} = k_1 x^4 + k_2 x^3 + k_3 x^2 + k_4 x + k_5, \tag{7}
\]

where \( x = b/R_d \). The values of the constants \((k_1 - k_5)\) are given in Table 1.

other models with positive densities at all points for discs as thick as \( b/R_d \sim 2.0 \), these models were significantly less accurate matches to radially exponential discs, and we will not consider them further.

### 2.3 Rotation curves with the 3MN models

In Fig. 3, we compare the rotation curve for an infinitely thin exponential disc (black dashed line) to those of the 3MN models from Table 1 (red solid line) and from Table 2 (blue dot–dashed line). Within four scalelengths, the rotation curves are all virtually indistinguishable. At large radius, the greater accuracy of the models in Table 1 is visible in comparison to the Table 2 models. We note that the negative densities arising in the Table 1 models, appear in the plane of the disc no closer than 8.0 scalelengths for an infinitely thin model. They have negligible effect on the rotation curve.

### 2.4 Useful conversion formulae

#### 2.4.1 Disc thickness \((b/R_d)\) and ellipticity \(e\)

To aid comparison with observed disc ellipticities, we measure how the ellipticity \(e\) of our disc models, seen edge-on, varies with disc thickness \(b/R_d\). We measure the ellipticity of contours containing 25, 50, and 75 per cent of the total mass, for a range of disc thickness from \(b/R_d = 0\) to 3. The results are shown in Fig. 4. In practice, the ellipticity changes very little whether we use the contour containing 25, 50 or 75 per cent of the total mass. This indicates the ellipticity of the 3MN model is only a weak function of radius. We fit the data points with a quadratic formula, shown by the blue dashed line in Fig. 4, giving ellipticity \(e\) as a function of disc thickness \(b/R_d\):

\[
e = -0.099(b/R_d)^2 + 0.599(b/R_d).
\]  

Solving equation (8), we obtain an expression for converting from disc thickness \(b/R_d\) as a function of ellipticity \(e\):

\[
b/R_d = 3.025 - 3.178\sqrt{0.906 - e}.
\]  

#### 2.4.2 Disc thickness to exponential and \(\text{sech}^2\) scaleheight

Our 3MN models have a single parameter controlling their thickness, \(b/R_d\). However, users are likely to be unfamiliar with \(b/R_d\) as a measure of thick ness. For this reason, we characterize this to scalelengths for more familiar vertical density distributions; an exponential, or a \(\text{sech}^2\) decay with \(z\).

We first sum up the fractional difference between the density of the 3MN model and the exponential, measured vertically out of the plane up to five scaleheights \((z = 0-5h)\), measured at \(R = 0\). We vary the disc thickness \(b/R_d\) in order to minimize the sum, and best match the exponential distribution. We then tabulate the best matches we find between \(b/R_d\) and \(h_z/R_d\) over a range of \(b/R_d\) from 0 to 3. We repeat this procedure to find the best match between 3MN discs and a \(\text{sech}^2\) vertical distribution. The best match is the same if we instead choose to compare the vertical density profiles at \(R = 2\) or \(4 R_d\).

The tabulated best matches are plotted in Fig. 5. The given formulae provide smooth fits through the tabulated data points. In each panel, the upper-left equation provides conversion to \(b/R_d\), while the lower-right equation provides conversion from \(b/R_d\).
3.2 The thin disc of the MW

We consider a radially exponential disc for the MW’s thin disc with a total mass of $M_t = 4.6 \times 10^{10} \, M_\odot$, and radial exponential scalelength $R_d = 2.2 \, \text{kpc}$ (Bovy & Rix 2013). We choose an exponential scaleheight of $h_z = 0.2 \, \text{kpc}$ (Larsen & Humphreys 2003), and Fig. 5 gives $b/R_d = 0.11$. Substituting $b/R_d$ into equation (7) with constants from Table 1, we get $M_{\text{SN},1} = 9.01 \times 10^{10} \, M_\odot$, $M_{\text{SN},2} = -5.91 \times 10^{10} \, M_\odot$, $M_{\text{SN},3} = 1.00 \times 10^{10} \, M_\odot$, $a_1 = 4.27 \, \text{kpc}$, $a_2 = 9.23 \, \text{kpc}$, $a_3 = 1.43 \, \text{kpc}$. This model matches a radially exponential disc to better than 0.5 per cent at $4 \, R_d$, and to better than 1.4 per cent at $10 \, R_d$.

3.3 The thick disc of the MW

For the thick disc, we consider a radially exponential disc with scalelength $R_d = 3.8 \, \text{kpc}$ and scaleheight $h_z = 0.9 \, \text{kpc}$ (Moni Bidin et al. 2012). Using Fig. 5 gives $b/R_d = 0.30$. We assume that the thick disc mass is $8.6 \, \%$ of the thin disc mass (Yoachim & Dalcanton 2006) so the total disc mass $M_t = 4.0 \times 10^{10} \, M_\odot$. Substituting $b/R_d$ into equation (7) with constants from Table 1 gives; $M_{\text{SN},1} = 7.88 \times 10^{9} \, M_\odot$, $M_{\text{SN},2} = -4.97 \times 10^{9} \, M_\odot$, $M_{\text{SN},3} = 0.82 \times 10^{9} \, M_\odot$, $a_1 = 7.30 \, \text{kpc}$, $a_2 = 15.25 \, \text{kpc}$, $a_3 = 2.02 \, \text{kpc}$. This model matches a radially exponential disc to better than 0.6 per cent at $4 \, R_d$, and to better than 1.4 per cent at $10 \, R_d$.

4 COMPARISON OF 3MN MODEL WITH OTHER DENSITY PROFILES

In Fig. 7, we analyse the 3MN thick disc model from Section 3.3 in more detail. In row (a)–(c), we compare cross-sections through the volume density distribution of the 3MN model (left), a double exponential (middle), and a radially exponential model whose density profile decays as sech$^2$ out of the plane (right). The scaleheight of the exponential and sech$^2$ distribution is the best match to the 3MN model, calculated using the equations in Fig. 5. Clearly, it is impossible for the 3MN model to exactly match the other profiles, as they are mathematically distinct. However, by comparing them we can judge how they differ, and the quality of the best matches provided in Fig. 5. Comparing along each row, the exponential disc is most ‘cuspy’ in the vertical direction, whereas the sech$^2$ is the most ‘cored’, and the 3MN model is found somewhere in between the other two. This is true whether the cross-section is made at (a) $y = 0R_d$, (b) $y = 2R_d$, or (c) $y = 4R_d$.

Row (d) provides a more quantitative analysis of the vertical density distribution up to $\sim 5b$, measured at (left) $R = 0R_d$, (centre) $R = 2R_d$, and (right) $R = 4R_d$. At small $z$ (less than roughly 2 or 3$b$), the 3MN density distribution roughly matches the other two profiles. However at greater distances from the plane, the 3MN model returns higher densities, and this becomes stronger if the vertical density profile is measured at larger $R$.

The upper panel of row (e) compares the surface density of the 3MN model (solid curve) to a radially exponential disc (dashed curve). Curves are plotted out to $R = 4R_d$. There is clearly an excellent agreement over this radius range, although it can be seen that the 3MN model returns slightly lower densities at very small radii ($R < 0.2R_d$). The lower panel indicates the absolute fractional difference in surface density between the two profiles. The maximum density difference is $\sim 15$ per cent at $R = 0$, but for $R > 0.2R_d$, the density difference is very low (typically $\sim 0.5$ per cent).
Figure 7. Analysis of the MW thick disc model of Section 3.3. Rows (a), (b), and (c) are cross-sections through the volume density distribution, and each row allows comparison between the 3MN model (left), a double exponential (middle), and a radially exponential model with a sech² density drop off out of the plane (right). Grey-scale colour bar units are $M_{\odot} pc^{-3}$. The plane of the disc lies on the $x$–$y$ plane, and slices are perpendicular to the plane at (a) $y = 0R_d$, (b) $y = 2R_d$, and (c) $y = 4R_d$. Row (d) is volume density with distance from the disc plane, measured at (left) $0R_d$, (centre) $2R_d$, and (right) $4R_d$. Different curves (indicated in key) compare the 3MN model, double exponential, and sech² model. The upper panel of row (e) compares the surface density profile of the 3MN model (solid curve) with a radially exponential disc (dashed curve) out to $4R_d$. The lower panel of row (e) shows the absolute fractional difference in the surface density of the two profiles at each radius.
5 SUMMARY AND CONCLUSIONS

We present a recipe for using a 3MN disc distribution to model the potential of a radially exponential disc. 3MN models have previously been used to model the disc component of the Milky Way. Here, we extend on this framework to allow its general application to discs of any mass, scalelength, and a wide range of thickness. We find parameters of the 3MN model that best match the mass distribution of a radially exponential disc. We consider a broad range of disc thicknesses from infinitely thin (ellipticity = 0.0), to near spherical (ellipticity = 0.9). The 3MN models have many benefits as they are entirely analytical, easy to implement, and provide continuous derivatives (enabling a calculation of accelerations) at all points.

(i) We provide accurate fitting formulae to our new 3MN models, that reproduce the mass distribution of a radially exponential disc to < 1.0 per cent out to 4\(R_d\), and < 3.3 per cent out to 10\(R_d\) for discs with a range of ellipticities from flat to near spherical (see equation 7 and Table 1).

(ii) We provide a second set of models in Table 2 that ensures positive densities at all positions for the disc thickness range \(b/R_d = 0.00–1.35\). This is equivalent to an ellipticity range from 0.0 to 0.6.

(iii) We provide a fitting formula to allow for easy conversion between the disc thickness \(b/R_d\) and disc ellipticity \(e\) (see equation 8), and in reverse (see equation 9).

(iv) The vertical distribution of our 3MN models is similar to an exponential or sech\(^2\) distribution at small \(z\). We provide a rough approximation for converting between disc thickness, exponential scaleheight, and sech\(^2\) scaleheight for \(z\) up to five scaleheights (see equations given in Fig. 5).

A user-friendly, online web-form is available at http://astronomy.swin.edu.au/~cflynn/expmaker.php. Users can request the disc thickness they require. The page will automatically provide the best matching 3MN parameters, calculated using our scheme. We acknowledge that better 3MN solutions may exist, hidden in the parameter space. In the future, we will extend on the techniques developed in this study in order to uncover alternative and potentially more accurate 3MN parameter sets, but also to allow for flared discs, and for alternative vertical density distributions.

ACKNOWLEDGEMENTS
