New & Noteworthy

We report for the first time that post-exercise cold-water immersion of one limb also enhances PGC-1α expression in a contra-lateral non-immersed limb. We suggest increased systemic β-adrenergic stimulation, and not localised cooling per se, exerts regulatory effects on local signalling cascades thereby modulating PGC-1α expression. These data therefore have important implications for research designs that adopt contralateral non-immersed limbs as a control condition, whilst also increasing our understanding of potential mechanisms underpinning cold-mediated PGC-1α responses.

Abstract

Mechanisms mediating post-exercise cold-induced increases in PGC-1α gene expression in human skeletal muscle are yet to be fully elucidated, but may involve local cooling effects on AMPK and p38 MAPK related signalling and/or increased systemic β-adrenergic stimulation. We aimed to therefore examine whether post-exercise cold-water immersion enhancement of PGC-1α mRNA is mediated through local or systemic mechanisms. Ten subjects completed acute cycling (8x5 min at ~80% peak power output) followed by seated-rest (CON) or single-leg cold-water immersion (CWI; 10 min, 8°C). Muscle biopsies were obtained pre-, post- and 3 h post-exercise from a single limb in the CON condition but from both limbs in CWI (thereby providing tissue from a CWI and non-immersed limb, NOT). Muscle temperature decreased up to 2 h post-exercise following CWI (-5°C) in the immersed limb, with lesser changes observed in CON and NOT (-3°C; \( P<0.05 \)). No differences between limbs were observed in p38MAPK phosphorylation at any time point (\( P<0.05 \)), whilst a significant interaction effect was present for AMPK phosphorylation (\( P=0.031 \)). Exercise (CON) increased gene expression of PGC-1α 3 h post-exercise (~5-fold; \( P<0.001 \)). CWI augmented PGC-1α expression above CON in both the immersed (CWI; ~9-fold; \( P=0.003 \)) and NOT limbs (~12-fold; \( P=0.001 \)). Plasma Normetanephrine concentration was higher in CWI vs. CON immediately post-immersion (860 vs. 665 pmol/L; \( P=0.034 \)). We report for the first time that local cooling of the immersed limb evokes transcriptional control of PGC1-α in the non-immersed limb, suggesting increased systemic β-adrenergic activation of AMPK may mediate, in part, post-exercise cold-induction of PGC-1α mRNA.

**Key Words:** PGC-1α, CWI, Normetanephrine, AMPK
**Introduction**

It is well established that the transcriptional co-activator peroxisome proliferator-activated receptor γ coactivator-1α (PGC-1α), the proposed “master regulator” of skeletal muscle mitochondrial biogenesis (37), is sensitively controlled by acute and chronic exercise (3, 4, 10, 36). Upstream control of PGC-1α includes phosphorylation by energy and stress sensing kinases AMP-activated protein kinase (AMPK) (23) and p38 mitogen-activated protein kinase (p38 MAPK) (2). Consistent with its initial discovery as cold-inducible (34, 38), recent studies have examined the potential of acute post-exercise cold exposure to also modulate PGC-1α expression. For example, in human tissue, both cold-ambient temperatures (42, 43) and post exercise cold-water immersion (18, 20) enhances the skeletal muscle PGC-1α gene transcription and protein translational response versus exercise alone. The precise mechanism(s) mediating cold-induced regulation of the PGC-1α transcriptional pathway have yet to be fully determined, though the cooling-induced alterations in muscle blood flow (14, 30) are unlikely to mediate these effects (33, 45). It is noteworthy, however, that chronic cold-induced changes in PGC-1α protein content arise in conjunction with increased activity of signalling kinases AMPK and p38 MAPK (18). These data suggest that cooling of the skeletal muscle tissue may play a role in mediating the post-exercise cold-induction of PGC-1α mRNA through activation of local signalling kinases.

Alternatively, systemic control via increased β-adrenergic activity is suggested to play a potent role in mediating the effects of cold exposure on PGC-1α expression via AMPK (29) and β2-adrenergic receptor (31) mechanisms. Indeed, plasma norepinephrine concentrations remain higher following high-intensity exercise after cold-water immersion versus control conditions (13). Studies to date have utilised the non-immersed limb as the control condition without the use of a true control (no cooling) condition (11, 18, 20). By assuming the response to cold-water immersion is mediated locally, such experimental designs do not
permit examination of the role of systemic versus localised mechanisms in mediating cold-induced changes in PGC-1α. Indeed, Ihsan et al. (20) observed that PGC-1α gene transcription was not induced in a non-immersed control limb, despite the limb having previously been exercised, and exercise being a potent stimulus to induce PGC-1α expression. This would therefore suggest that an induction of PGC-1α expression in an immersed limb occurred by way of cold-induced mechanisms. In this regard, we suggest that the increased systemic β-adrenergic activity associated with post-exercise cooling of the immersed limb could also modulate PGC-1α expression in the non-immersed contralateral limb.

Therefore, the aim of the present study was to examine whether the cold-water induced increase in PGC-1α mRNA observed post exercise is mediated through local or systemic mechanisms. To this end, we employed a novel experimental design (in a repeated measures crossover design) where ten recreationally active males completed an acute cycling protocol (8x5 min at ~80% peak power output) followed by a seated-rest condition (CON) or single-leg cold-water immersion (CWI; 10 min, 8°C). Muscle biopsies were obtained pre-, post- and 3 h post-exercise from a single limb in the CON condition but from both limbs post-exercise in the CWI trial (thereby providing tissue from a CWI and non-immersed limb, NOT). In this way, our design allowed us to obtain tissue from true control conditions but yet, also sample tissue from an immersed and non-immersed limb that was subject to the same hormonal milieu.

Methods

Subjects. Ten recreationally active healthy males (age 26 ± 4 y; body mass 79.29 ± 6.73 kg; height 180 ± 5 cm; \( \dot{V}O_{2\text{peak}} \) 51.46 ± 9.07 mL.kg\(^{-1}\).min\(^{-1}\); peak power output (PPO) 265.2 ±
38.33 W; mean ± SD) participated in this study. Subjects were instructed to refrain from exercise, alcohol and caffeine 48 hours prior to the test day. All subjects gave written informed consent to participate after details and procedures of the study had been fully explained. Subjects had no history of neurological disease or musculoskeletal abnormality and none were under any pharmacological treatment during the course of the study. Each subject was medically screened by a practising GP prior to participation for their individual risk associated with high-intensity exercise, muscle biopsy procedures and immersion in cold water. All procedures performed in the study were approved by the Ethics Committee of Liverpool John Moores University and in accordance with the 1964 Helsinki declaration and its later amendments.

Experimental Design. In a repeated-measures crossover design, subjects completed two high-intensity intermittent cycling protocols followed either by 10 min seated rest (CON) or single-leg CWI (10 min at 8°C). Muscle biopsies were obtained from the vastus lateralis immediately before, post- and 3 h post-exercise. During the CWI trial muscle biopsies in the post-exercise period were taken from both the immersed and non-immersed leg. This design allowed us to assess the impact of the cold stimulus locally (immersed leg) and systemically (non-immersed leg) against a relevant resting control. Both experimental trials were conducted in a counterbalanced, randomized order with at least 10 days between conditions.

Experimental Protocol. Subjects attended the laboratory on 3 separate occasions. On the first occasion, subjects completed an incremental exercise test to fatigue for the determination of \( \dot{V}O_{2}\text{max} \) and PPO (15). Results from this test were used to determine the power output necessary for cycling at a proportion of PPO on subsequent test days (detailed below). Prior to the first test day, subjects completed a 24-hour food diary to be replicated before the second trial. Upon arrival at the laboratory (0900h) subjects were fitted with a heart-rate monitor (Polar RS400, Kempele, Finland), skin and rectal temperature probes (MHF-18050-
A and MRV-55044-A, Ellab, Rodovre, Denmark). Legs were marked for subsequent insertion of muscle temperature needles; area of insertion was calculated as half the length of the femur, over the ‘belly’ of the vastus lateralis. The needle thermistor was then placed at a depth of 3cm, plus one-half of the skinfold measurement, for the determination of deep muscle temperature (3cm). Following 10-min resting in a supine position, baseline measures of heart rate (HR), temperature and oxygen uptake ($\dot{V}O_2$; Oxycon Pro, Jaeger, Wuerzburg, Germany) were assessed. Resting venous blood samples were drawn from a superficial vein in the anti-cubital crease of the forearm using venepuncture cannulation (BD Nexiva Closed IV Catheter 22G Blue, Becton Dickinson, Oxford, UK). Resting muscle temperature was assessed using a needle thermistor (13050; Ellab, Rodovre, Denmark) inserted into the vastus lateralis at 3cm depth as previously described (30). Finally, resting muscle biopsy samples from the vastus lateralis (~30–50 mg wet wt) were obtained under local anaesthesia (0.5% marcaine) using a Pro-Mag 2.2 biopsy gun (MD-TECH, Manan Medical Products, Northbrook, IL). At rest only a single leg was biopsied in the cooling trial (CWI) in attempt to reduce the stress experienced by subjects. This leg was randomised between the immersed and non-immersed limbs to exclude potential variation caused by leg dominance; all subsequent biopsies were completed in both legs, at each time point, 2cm proximal to the previous incision.

Following the resting biopsy, subjects completed a high-intensity intermittent cycling protocol consisting of $8 \times 5$ min bouts at 82.5% PPO separated by 1 min rest (adapted from 44) followed by either single-legged CWI (CWI: 10 min at 8°C; NOT: non-immersed leg i.e. 10 min at room temperature) or a control condition (CON; seated rest). CWI was conducted using a specialised seated mechanical hoist to lower the subject so that one leg was placed inside the cold-bath, allowing the other (NOT) to remain outside, and dry. Subjects then recovered in a semi-reclined position under normal laboratory temperatures (~21°C) until 3-
hours post-exercise. Measures of heart rate, skin temperature (thigh and calf) and rectal temperature were recorded throughout the exercise and recovery periods. Oxygen uptake was measured during the final minute of each high-intensity bout of exercise, during immersion, immediately post-immersion and again at 1, 2 and 3 h post-exercise. Ratings of perceived exertion (RPE) were assessed during the final minute of each exercise bout (5), whilst subjective measures of perceived shivering were assessed throughout water immersion and the 3h recovery period using a visual analogue scale from 1 (No shivering) to 5 (Intense Shivering) (24). Laboratory temperatures remained stable throughout (21.18 ± 0.76°C) and at no point were subjects allowed to rub themselves dry or shower (changing into dry shorts after immersion was allowed). Subjects were advised to wear the same clothes between trials. Muscle temperature was assessed post-exercise, immediately post-immersion and at 1, 2 and 3h post-exercise. Venous blood samples were also drawn at these times. Bi-lateral muscle biopsies occurred immediately after exercise and 3h post-exercise.

Venous blood samples were drawn from a superficial vein in the anti-cubital crease of the forearm using standard venepuncture techniques (BD Nexiva Closed IV Catheter 22G Blue, Becton Dickinson, Oxford, UK). Blood samples (~10ml) were collected into vacutainer tubes (Becton Dickinson, Oxford, UK) containing EDTA and stored on ice until centrifugation at 1500 rev.min⁻¹ for 15-min at 4°C. Following centrifugation, aliquots of plasma were stored at -80°C for later analysis. Plasma metanephrine and Normetanephrine concentrations were measured using liquid chromatography tandem mass spectrometry as previously described (35). All samples were analysed in duplicate, with the mean value employed.

rt-qRT-PCR. Skeletal muscle samples (~30 mg) were transferred to 2 ml lysing tubes containing 1.4 mm ceramic beads (Lysing Matrix D, MP Biomedicals, UK) containing 1 ml ice-cooled TRI-reagent (Life Technologies Ltd, UK) and homogenised at 6 m/s for 3 x 40 seconds, separated by 5 minutes cooling on ice (MP Fastprep-24, MP Biomedicals, UK).
RNA was extracted according to the TRI-reagent manufacturer’s instructions. RNA concentration and purity were assessed by UV spectroscopy at ODs of 260 and 280 nm using a Nanodrop 3000 (Fisher, Roskilde, Denmark). A target of $A_{260} / A_{280}$ ratio was set at 1.8 to 2.2. Seventy ng RNA was used for each PCR reaction. Primer sequences (Table 1) were identified using Gene (NCBI, http://www.ncbi.nlm.nih.gov.gene) and designed using Primer-BLAST (NCBI, http://www.ncbi.nlm.nih.gov/tools/primer-blast). Sequence homology searches ensured specificity and that all primers had no potential unintended targets. The primers were ideally designed to yield products spanning exon-exon boundaries to prevent any amplification of gDNA. Three or more GC bases in the last five bases at the 3’ end of the primer were avoided. Secondary structure interactions (hairpins, self-dimer and cross dimer) within the primer were avoided. All primers were between 16 and 25 bp, and amplified a product of between 67-212 bp. Primers were purchased from Sigma (Suffolk, UK).

rt-qRT-PCR amplifications were performed using QuantiFast™ SYBR® Green RT-PCR one step kit on a Rotor-gene 3000Q (Qiagen, Crawley, UK) supported by rotor-gene software (Hercules, CA, USA). rt-qTR-PCR was performed as follows: hold 50°C for 10 min (reverse transcription/cDNA synthesis), 95°C for 5 min (transcriptase inactivation and initial denaturation step) and PCR steps of 40 cycles; 95°C for 10s (denaturation), 60°C for 30s (annealing and extension). Upon completion, dissociation/melting curve analysis were performed to reveal and exclude non-specific amplification or primer-dimer issues (all melt analysis in this study presented single reproducible peaks for the reference gene and each target gene suggesting amplification of a single product). Following initial screening of suitable reference genes, GAPDH showed the most stable $C_t$ values across all RT-PCR runs, subjects and regardless of experimental condition ($23.54 \pm 1.69$ $C_t$; 7% Co-efficient of variation) and was selected as the reference gene in all RT-PCR assays. The average PCR efficiency was 90% and variation for all genes was less than 4.3%. The relative gene
expression levels were calculated using the comparative C\textsubscript{i} (\(\Delta\Delta C\textsubscript{i}\)) equation (41) where the relative expression was calculated as \(2^{-\Delta\Delta Ct}\) and where \(C\textsubscript{i}\) represents the threshold cycle. mRNA expression for all target genes was calculated relative to the reference gene (GAPDH; subject’s own samples reference) within same subject and condition and to a calibrator of Pre-exercise.

**SDS-PAGE and Western Blotting.** Approximately 30 mg of frozen muscle was homogenized using 2.4 mm ceramic beaded tubes (6 m/s for 3 x 40 seconds, separated by 5 minutes cooling on ice; MP Fastprep-24, MP Biomedicals, UK), in 500 µl of ice-cold lysis buffer [25 mM Tris·HCl (pH 7.4), 50 mM NaF, 100 mM NaCl, 5 mM EGTA, 1 mM EDTA, 10 mM Na-pyrophosphatase, 1% Triton X-100] and supplemented with a protease phosphatase inhibitor cocktail (Halt Protease and Phosphatase Inhibitor 186 Cocktail, Thermo Scientific, #78442). The resulting homogenates were centrifuged at 14,000 g for 10 min at 4°C, and the supernatant was collected. The protein content of the supernatant was determined using a bicinchoninic acid assay (Sigma, UK). Each sample was diluted with an equal volume of 2X Laemmli buffer (National Diagnostics) and boiled for 10 min at 100°C. Forty µg of total protein from each sample was loaded (65 µg for phosphorylated analytes) and then separated in Tris-glycine running buffer (10x Tris/glycine, Geneflow, Staffordshire, UK) using self-cast 10% separating [33% Protogel; (30% w/v acrylamide: 0.8% (w/v) Bis-Acrylamide stock solution (37.5:1)), 25% Protogel resolving buffer (1.5M Tis-HCL, 0.4% SDS, pH 8.8), 41% ddH\textsubscript{2}O, 100µl 10% APS, 20µl TEMED] and 4% stacking [13% Protogel, 25% Protogel Stacking buffer (0.5M Tris HCL, 0.4% SDS, pH 6.8), 61% ddH\textsubscript{2}O, 100µl 10% APS, 20µl TEMED] gels (National Diagnostics, Geneflow, UK). Gels were transferred semidry onto nitrocellulose membrane (Transblot Turbo, BioRad) for 30 min at 25V and 1.0 mA in transfer buffer [10% TRIS/glycine (Sigma), 20% methanol, 70% ddH\textsubscript{2}O). After transfer, membranes were briefly washed in TBST (0.19 M Tris pH 7.6, 1.3 M NaCl, 0.1%
Tween-20] before being blocked for 1 h at room temperature in TBST with 1% BSA. The membranes were then washed for 3 x 5 min in TBST before being incubated overnight at 4°C with antibodies for anti-phospho-AMPK Thr172 (cat no: 2532), p38 MAPKThr180/Tyr182 (cat no: 9211) (Cell Signalling) as well as total protein content of AMPK (cat no: 2531), p38 MAPK (cat no: 9212) (Cell Signalling, UK), GAPDH (25778; Santa Cruz), and PGC-1α (Calbiochem, Merck Chemicals, UK) all at concentrations of 1:1000 in 1 x TBS. The following morning, membranes were washed for a further 3 x 5 min in TBST and subsequently incubated with goat anti-rabbit horseradish peroxidase-conjugated secondary antibody (Bio-Rad, UK) for 1 h at room temperature. After a further 3 x 5 min washes in TBST, membranes were exposed in a chemiluminescence liquid (SuperSignal, Thermo Fisher Scientific, Rockford, IL) for 5 min (30 sec for GAPDH). Membranes were visualized using a Bio-Rad Chemi-doc system, and band densities were determined using Image Lab image-analysis software (Bio Rad, UK). Samples from each subject for all exercise conditions were run on the same gel and statistical analysis conducted on raw densitometry data. Phosphorylated AMPK Thr172 and p38 MAPK Thr180/Tyr182 were normalised to their total protein, as these did not change significantly across blots or samples ($P > 0.05$). PGC-1α was normalised to GAPDH.

**Statistical analysis.** All data are presented as mean ± SD, unless otherwise stated. Baseline data, distance cycled, exercise HR and RPE were compared between conditions using a Paired Samples T-test. A two-factor (two condition × time) within-participants general linear model was used to evaluate the effect of time (baseline v post exercise) with shared baseline data used for NOT and CWI (Statistical Package for the Social Sciences version 21.0; SPSS Inc., Chicago, IL). A two-factor (three condition × time) within-participants general linear model was subsequently used to evaluate the influence of the cooling intervention following exercise and the 3 h post exercise period. The main effects for condition and time was
followed up using planned LSD multiple contrasts. Where a significant condition by time interaction was observed, the post exercise to 3h post exercise change scores were calculated and compared across the 3-conditions using LSD multiple contrasts. The ES magnitude was classified as trivial (<0.2), small (>0.2-0.6), moderate (>0.6-1.2), large (>1.2-2.0) and very large (>2.0-4.0) (17). The α level for evaluation of statistical significance was set at $P < .05$.

Results

Exercise Response.

Distance cycled (CON 32.52 ± 4.21 km, CWI 32.33 ± 4.33 km; $P = 0.629$, ES 0.04 Trivial), heart rate ($P = 0.309$, ES 0.13 Trivial), $\dot{V}O_2$ (ml/kg.min$^{-1}$; $P = 0.855$, ES 0.02 Trivial) and RPE ($P = 0.637$, ES 0.08 Trivial) were similar between CON and CWI trials (data not shown). Mean HR during the final minute of exercise was 182 ± 8 beats.min$^{-1}$ in CON and 183 ± 8 beats.min$^{-1}$ in CWI, equating to ~94% HR max. The RPE in the final exercise bout was 19 ± 1 AU and 19 ± 1 AU in the CON and CWI trials respectively.

Recovery Response.

Metabolic Responses. Heart rate (ES 0.90 Moderate) and $\dot{V}O_2$, (ES 1.20 Moderate) was higher in CWI vs CON during the post-exercise recovery period (Table 2; $P < 0.001$). The change in HR and $\dot{V}O_2$, over time was also different between conditions ($P <0.001$) with increases in HR and $\dot{V}O_2$, occurring during the initial 2 minutes of immersion. Following immersion, HR and $\dot{V}O_2$ dropped below pre-immersion values and remained lower.
throughout the 3h recovery period (HR, ES >0.92 Moderate; $\dot{V}O_2$, ES >1.25 Large) ($P < 0.05$).

**Thermoregulatory Responses.** Rectal temperature was similar between conditions throughout the post-exercise period (CON 37.52 ± 0.24°C, CWI 37.48 ± 0.05°C, ES 0.49 Small, $P = 0.217$. The change in rectal temperature over time was different between conditions, with a small decline in rectal temperature occurring after 3 minutes of immersion until 3h post-exercise ($P=0.034$, ES >0.22 Small). Thigh skin temperature was generally lower throughout the post-exercise recovery period in CWI versus CON (ES 6.26 Very Large) and NOT (ES 6.46 Very Large) (Figure 1a, $P < 0.001$). The change over time was also different between conditions, with thigh skin temperature continually decreasing in CWI and remaining lower than pre-immersion values until 1h post exercise (ES 3.0 Very Large, $P < 0.001$). Values in CON and NOT limbs remained similar to pre-immersion throughout the 3h recovery period ($P = 0.10$, ES 0.57 Small).

Post-exercise muscle temperature (3 cm depth) was similar between CON (38.75°C), CWI (38.86°C) and NOT (38.54°C) (Figure 1b; $P > 0.05$). During the 3 h recovery period muscle temperature (3cm) was lower in CWI versus CON (ES 1.60 Large) and NOT (ES 1.77 Large) ($P < 0.001$). The change in muscle temperature over time was also different between conditions ($P < 0.001$). Muscle temperature declined to a large extent immediately after immersion in the CWI limb, followed by a further gradual reduction during the remaining 3h post-exercise period ($P < 0.001$). In CON and NOT conditions, muscle temperature was reduced to a lesser extent immediately following immersion followed by a further gradual reduction during the 3h post-exercise period ($P = 0.246$, ES 0.34 Small) (See Figure 1b).

Subjective shivering ratings were greater in CWI vs CON during the post-exercise recovery period (ES 1.20 Large, $P = 0.067$). The change in shivering over time also tended to be
different between conditions \((P = 0.062)\), with ‘slight’ shivering observed in the CWI condition during the first 2 minutes following immersion \((ES >0.60 \text{ Moderate})\). Slight shivering was also observed 2h post exercise in the CWI condition \((ES 0.95 \text{ Moderate})\).

**AMPK and P38 MAPK activity and total abundance**

Phosphorylation of AMPK\(^{\text{Thr172}}\) was not increased post-exercise \((P = 0.242, ES 0.20 \text{ Small})\).

At post-exercise and 3h post-exercise phosphorylation of AMPK\(^{\text{Thr172}}\) was similar between conditions \((P = 0.846, ES 0.03 \text{ Trivial})\). However, the change in AMPK\(^{\text{Thr172}}\) between these time points was different between conditions \((P = 0.031; \text{ Figure 2})\). AMPK\(^{\text{Thr172}}\) phosphorylation increased in CWI vs. CON \((P = 0.027, ES 1.22 \text{ Large})\) with a moderate increase in AMPK\(^{\text{Thr172}}\) phosphorylation also observed in NOT vs. CON \((P = 0.145, ES 0.70 \text{ Moderate})\). Representative Western blots are shown in Figure 5.

Exercise induced a small increase in phosphorylation of p38MAPK\(^{\text{Thr180/Tyr182}}\) \((P = 0.056, ES 0.44 \text{ Small, Figure 3})\). At post exercise and 3h post-exercise phosphorylation of p38MAPK\(^{\text{Thr180/Tyr182}}\) was similar between conditions \((P = 0.672; \text{ ES 0.03, Trivial})\). No differences in the change in phosphorylation between these time points was observed between conditions \((P = 0.268, \text{ Figure 3})\). Representative Western blots are shown in Figure 5.

**PGC-1alpha mRNA and protein abundance.**

PGC-1\(\alpha\) mRNA expression was moderately increased with exercise \((P = 0.066, ES 0.92 \text{ Moderate, Figure 4a})\). At 3h post-exercise, expression was greater in CWI \((ES 1.2 \text{ Moderate, } P = 0.003)\) and NOT \((ES 1.6 \text{ Large, } P = 0.001)\) versus CON, but was similar between CWI and NOT \((ES 0.6 \text{ Small, } P = 0.141)\) \((\text{Figure 4a})\). This reflected the greater change in expression in CWI and NOT conditions between post exercise and 3h post exercise time.
points ($P = 0.001$, Figure 4a). PGC-1α protein content was not influenced by exercise ($P = 0.092$) or CWI ($P = 0.471$, Figure 4b). Representative Western blots are shown in Figure 5.

**Additional gene expression**

Exercise induced increases in SIRT1 ($P = 0.057$, ES 0.8 Moderate) and NRF2 ($P = 0.028$, ES 0.6 Moderate) mRNA (data not shown). No changes were seen between conditions, or between conditions over time ($P > 0.05$). Gene expression analysis for p53, COXIV, CS, TFAM, SIRT1, NRF2 and ERRα mRNA was not influenced by exercise or CWI ($P > 0.05$; data not shown).

**Plasma Metanephrine and Normetanephrine.**

Metanephrine concentrations were similar between conditions ($P = 0.159$, ES 0.15 Trivial). The change in metanephrine over time was also similar between conditions ($P = 0.299$). Metanephrine concentration was increased post-exercise (ES 2.46 Very Large) and post-immersion (ES 0.77 Moderate) vs. baseline ($P \leq 0.02$). Normetanephrine values were greater in CWI vs. CON ($P = 0.034$, ES 0.43 Small) with the largest difference seen post-immersion (860 vs. 665 pmol/L, CWI vs. CON, respectively). The change in Normetanephrine over time was similar between conditions ($P = 0.821$). Normetanephrine concentrations increased with exercise (ES >4.70; $P < 0.001$) and remained above baseline post-immersion (ES 1.52 Large) and 1hr post-exercise (ES 1.06 Moderate) ($P <0.001$). Concentrations returned to baseline at 2hr post-exercise (See Table 3).

**Discussion**
The aim of the present study was to examine whether the post-exercise cold-water induced increase of PGC-1α mRNA is mediated through local or systemic mechanisms. Using a novel experimental design, we report for the first time the appearance of systemic “cross-talk” between immersed and non-immersed limbs, as evidenced by the similar increase in PGC-1α mRNA in these limbs after single-legged CWI. Additionally, we suggest that this effect could be mediated by β-adrenergic induced stimulation of AMPK. In addition to providing novel data on the potential mechanisms mediating post-exercise cold-induced enhancement of PGC-1α expression, our data also have potential implications for research designs that utilise as non-immersed limbs as control conditions.

Since its initial discovery (38) the importance of the post-exercise PGC-1α response to the oxidative adaptive process has been examined extensively, with mRNA increases ranging 5 to 10-fold commonly observed at 3-4 hours following exercise (3, 4, 21, 36). More recently, cold-ambient temperatures (42, 43) and post exercise cold-water immersion (18-20, 24), have also been shown to enhance (~2- to 4- fold greater) the skeletal muscle PGC-1α gene transcription and protein translational response versus exercise alone. In line with such observations, the high-intensity intermittent cycling protocol used in the present study elicited a ~5-fold increase in PGC-1alpha mRNA at 3 hours post-exercise. Furthermore, CWI enhanced this response to a greater extent than exercise alone (~9-fold increase vs. Pre in the CWI immersed limb).

There have been suggestions that reduced tissue temperature may be responsible for the differences observed between cold-treated and control limbs. This stems from the initial discovery that PGC-1alpha was cold inducible in animals (6, 9, 38). In humans, recent data from Ihsan and colleagues (18, 20) implicates a reduction in tissue temperature in the cold-induced increases of PGC-1α, as increases in mRNA (3h post-exercise) and protein content (after 4 weeks of training) were seen only in a cooled limb, and not in the contralateral non-
immersed limb. Potential mechanisms underpinning such responses include activation of non-noxious thermoreceptors via reduced skin temperature (Hensel & Boman, 1960, 22).

Within the present study, both the NOT and CWI limbs displayed similar acute PGC-1α mRNA expression in the 3 h recovery period, whilst skin and muscle temperature were significantly reduced in the CWI limb only. Indeed, the non-immersed limb (NOT) showed a similar temperature profile (skin and muscle temperature) to that of CON, where the magnitude of PGC-1α mRNA response was almost half when compared with CWI and NOT. When taken together, these data suggest that alterations to local muscle temperature do not play a significant role in cold-induced regulation of PGC-1α expression.

As a result of increased local PGC-1α gene expression in the non-immersed exercised limb to a similar magnitude as the immersed limb, we sought to consolidate the role of the upstream kinases AMPK and p38-MAPK (7, 23, 47) in their ability to regulate PGC-1α transcription. p38MAPK is a stress activated kinase that has been shown extensively to be phosphorylated after acute exercise, independent of intensity (10). Moreover, p38MAPK can exert its effect upon PGC-1α transcription via upregulated ATF2 activity at the PGC-1α promoter (2). In the current study, exercise induced a small (ES 0.44, 1.5-fold) increase in phosphorylation with no further response to cooling. Moreover, our data supports previous data showing acute post-exercise phosphorylation of p38MAPK locally in skeletal muscle tissue occurs systemically (46). Exercise-induced intensity dependant AMPK phosphorylation is a well reported phenomenon (8, 12, 28) in rodent and human studies (34, 10). Moreover, AMPK is implicated in PGC-1α activity via direct phosphorylation, initiating many of the important gene regulatory functions of PGC-1α in skeletal muscle (23). The post-exercise increase in phosphorylation of AMPK in the present study was similar in magnitude to previous work (3) from our laboratory, albeit failing to achieve statistical significance. Notwithstanding this, large and moderate effect sizes were observed at 3 h post-exercise in the CWI and NOT limbs
These greater increases from post-exercise to 3 h post-exercise in the immersion trial (CWI and NOT limbs), compared to a slight decline in CON suggest the increases in phosphorylation of AMPK during the post-cooling period are controlled by a systemic mechanism, possibly adrenergic control via cold-augmented plasma Normetanephrine.

Epinephrine and norepinephrine are both dual α- and β- adrenergic agonists. Previous in vivo and in vitro incubation techniques utilising α- and β- adrenergic agonists have reported increased AMPK activation in rodent skeletal muscle (32), adipose tissue (26) and cell cultures (48) implicating catecholamines as a potential AMPK activator. Despite this, support for the above hypothesis is currently conflicting, and is limited by distinct differences in methodological design and species studied. In rodent muscle, acute infusion of adrenergic agonists/antagonists have previously shown to be ineffective at altering PGC-1α transcriptional activity (39, 40) and its upstream effector p38-MAPK (25). In contrast, treatment with β-adrenergic agonists/antagonists has been shown to induce and inhibit PGC-1α respectively (31), whilst incubation of rodent skeletal muscle with the adrenergic agonist phenylephrine increased the activity of the upstream regulator of PGC-1α, AMPK (32). When results from these studies are taken together, it could be suggested that adrenergic activation of AMPK is a potential mechanism to explain the systemic increases in PGC-1α gene expression described herein.

In humans, one study has investigated the impact of higher catecholamine levels on AMPK phosphorylation in human skeletal muscle (27). These authors assessed muscle biopsies from an exercised and non-exercised limb in conditions of heightened catecholamine release. Results showed AMPK activity was restricted to contracting muscle only, with no systemic effects notable in the non-exercised limb despite the increased catecholamine levels. Importantly, in our study all limbs were exercised before undergoing cold exposure. It
therefore may be that the cold induction of β-adrenergic pathways (via increased
catecholamines) presented in this manuscript allows an additive response to exercise
stimulated AMPK phosphorylation. Further studies are now required to verify this signalling
response in related experimental conditions in human skeletal muscle.

Another pathway by which increased catecholamine’s may enhance PGC-1α transcription is
via increased activation of β-adrenergic receptors. Activation of these receptors increases
intracellular cAMP, which could ultimately activate CREB function on the PGC-1α promoter
(1). However, evidence exists to show β-adrenergic stimulation does not activate a
p38MAPK - ATF2 - CREB - PGC-1α signalling axis in skeletal muscle (25). These findings
resonate with results from the present study as no changes in phosphorylation of p38MAPK
were observed alongside increased plasma Normetanephrine concentrations. Further work is
required to investigate the influence of the dual stress of exercise and cold temperature upon
this signalling axis.

Downstream of PGC-1α, Slivka and colleagues (42) noted that recovery in cold ambient
temperatures (4h in 7°C ambient air) reduced the expression of the transcription factors
Nuclear-respiratory factor 2 (NRF2) and estrogen-related receptor α (ERRα), whilst having
no effect on mitochondrial transcription factor a (TFAM). Their importance to the adaptive
response is highlighted by their roles in oxidative metabolism. Our data suggest the
immersion protocol used herein was not sufficient to induce such changes. Indeed, 10
minutes of single-legged immersion offers a much smaller cooling stimulus than the 4 hours
in cool ambient temperatures, as used by Slivka et al. (42). In addition, an acute increase in
PGC-1α gene expression was not followed by changes in PGC-1α total protein content,
perhaps due to the acute time-frame of sampling applied in the present study. With this lack
of change in total protein content it is however, unlikely that changes in gene expression of
downstream genes such as NRF2, TFAM, COXIV, CS, ERRα presented here, would be
affected by its upstream protein function as a transcription factor (PGC-1α). More research is required to understand the effect and dose response of a cold stimulus on downstream targets of PGC-1α.

It is difficult to explain the differences in PGC-1alpha mRNA results between the present study and Ihsan et al. (20), particularly the difference in non-immersed limbs. Moreover, reasons as to why Ihsan and colleagues failed to see the expected exercise-induced response in their non-immersed control limb, with minor changes from baseline at 3h post-exercise (1.5-fold increase vs. 3-5-fold increase usually seen), remain unclear. One possible explanation might include the differing muscle recruitment patterns occurring between the exercise protocols utilised (cycling vs. running). Ultimately, results from the present study have future implications on scientific study designs. Those wishing to investigate cold induced post-exercise responses in skeletal muscle must be aware of the evidence that implicates a systemic response of Normetanephrine, and a local response of p-AMPK in both immersed and non-immersed limbs. Further evidence is required to support the impact of systemic transcriptional responses in unilateral research designs, as such designs may be liable to error; potentially underestimating the actual response occurring in the immersed limb if relativized to a non-immersed limb instead of a resting control. Ultimately, the choice of scientific design lies with the question posed, as contralateral designs remain useful for understanding both local and systemic responses.

In summary, the present study characterises for the first time the mechanistic control of cold induced PGC-1α mRNA expression. Data herein indicate a reduction in tissue temperature (2-3°C) plays a limited role as similar levels of PGC-1α mRNA expression are observed in an immersed and non-immersed limb despite a reduction in tissue temperature in the CWI limb only. Moreover, a cold-induced systemic increase in plasma Normetanephrine may impact localised phosphorylation events of the signalling kinase AMPK^Thr172, with potential
downstream effects upon rates of PGC-1α mRNA expression. Future studies should investigate the role of β-adrenergic receptors in Normetanephrine induced AMPK phosphorylation and the signalling role of MEF2 and CRE/ATF2 sites to confirm a link between catecholamines and PGC-1α. Moreover, due to the acute nature of the present study more work is required to investigate whether the response seen herein is maintained over a more chronic term.

Acknowledgements

All work was conducted at Liverpool John Moores University. Analysis of catecholamines was conducted by John Dutton at UEA. The authors would like to thank Dean Morrey and Gemma Miller for their assistance in laboratory co-ordination and Kelly Hammond and Chris Mawhinney for their assistance in data collection.

Disclosures

The authors report no conflicts of interest.
