ABSTRACT

Introduction: This study involved an analysis of the impact of mental fatigue on heart rate recovery (HRR), subjective measures of fatigue and intermittent running performance in handball players. **Objective:** This study was aimed at (1) examining the effects of an induced state of mental fatigue on the aerobic performance of handball players, as measured by the Yo-Yo IR1 test, and (2) exploring possible changes in heart rate regulation through HRR analysis. **Methods:** Twelve handball players (age: 17.50 ± 3.63 years; 5 ± 2.2 years of practice) undertook a Yo-Yo IR1 test on two occasions, separated by an interval of at least 72 hours. The Yo-Yo IR1 test was preceded by a 30-min treatment, consisting of the Stroop Color-Word Test, to induce mental fatigue. Participants in the control condition watched an emotionally neutral video. **Results:** Higher ratings of mental fatigue and mental effort following the Stroop Test were observed for the experimental group. No differences in motivation were observed between conditions. Moreover, the induction of mental fatigue impaired running performance and led to a higher RPE during the Yo-Yo IR1 test. Notwithstanding, no changes in HRR or blood lactate levels were observed across conditions. **Conclusion:** Altogether, these results suggest that mental fatigue impairs intermittent running performance, without affecting HRR values. **Level of Evidence III; Case-Control study.**

Keywords: Mental fatigue; Athletic performance; Exercise tolerance; Fatigue; Exercise test.

RESUMO

Introdução: Este estudo envolveu uma análise do impacto da fadiga mental sobre a recuperação da frequência cardíaca (RFC), medidas subjetivas de fadiga e desempenho de corrida intermitente em jogadores de handebol. **Objetivo:** Este estudo visou (1) examinar os efeitos de um estado induzido de fadiga mental no desempenho aeróbico de jogadores de handebol, medido pelo teste Yo-Yo IR1 e (2) explorar possíveis alterações na regulação da frequência cardíaca através da análise da RFC. **Métodos:** Doze jogadores de handebol (idade: $17,50 \pm 3,63$ anos, $5 \pm 2,2$ anos de prática) realizaram um teste Yo-Yo IR1 em duas ocasiões, com pelo menos 72 horas de intervalo. O teste Yo-Yo IR1 foi precedido por tratamento de 30 minutos que consistiu no teste Stroop Color-Word para induzir estado de fadiga mental. Os participantes na condição de controle assistiram a um vídeo emocionalmente neutro. **Resultados:** Foram observadas taxas mais elevadas de fadiga mental e esforço mental após o teste Stroop para o grupo experimental. Não foram observadas diferenças na motivação entre as condições. Além disso, a indução de fadiga mental prejudicou o desempenho de corrida e levou a maior PSE durante o teste Yo-Yo IR1. Não obstante, não foram observadas alterações na RFC nem nas concentrações de lactato sanguíneo entre as condições. **Conclusão:** Em conjunto, esses resultados sugerem que a fadiga mental afeta o desempenho de corrida intermitente, sem alterar os valores de RFC. **Nível de Evidência III; Estudo de caso-controle.**

INTRODUCTION

Handball is an intermittent sport, with specific requirements according to the players' positions.^{1,2} To this extent, mental fatigue has been described as an intervening factor affecting athletic performance.³ As such, advancing research about fatigue in handball is paramount, as mental fatigue can impair information processing and decision-making, ultimately impairing performance.

Mental fatigue is conceptualized as a psychobiological state induced by sustained periods of demanding cognitive activity and characterized by feelings of tiredness and lack of energy.^{4,5} Within sports, previous research has shown that a 30-minute cognitive task impairs subsequent physical, technical, and decision-making performance among soccer players.^{6,7} However, to the best of our knowledge, no research has examined the influence of mental fatigue on performance in handball players.

In endurance sports,^{5,8} an induced state of mental fatigue has been shown to reduce performance. These negative effects on performance have been attributed to higher ratings of perceived exertion (RPE). In other words, when mentally fatigued, individuals perceive the same given stimulus as more effortful than in control situations,^{9,10} thus reducing one's exercise tolerance.

Although mental fatigue impairs physical performance, mental fatigue has not been linked to changes in physiological variables, such as heart rate and blood lactate concentrations in intermittent activities.^{5,9} Previous studies have shown that mental fatigue can impair muscular recovery¹¹ and alter the autonomic regulation of heart rate.^{12,13} However, as far as we are concerned, no previous study has tested whether mental fatigue alters heart rate recovery (HRR) after different exercise conditions.

The analysis of HRR is relevant to studies in mental fatigue for various reasons. First, HRR is a non-invasive marker of autonomic control of the heart that results from a coordinated interaction between sympathetic withdrawal and parasympathetic re-activation.¹⁴ Second, in sport and exercise settings, HRR is a reliable marker of athletic performance¹⁵ and Negative changes in HRR are indicative of insufficient recovery which, in turn, leads to decreased athletic performance.^{16,17}

In light of the aforementioned, the purposes of this study were to (1) examine the effects of an induced state of mental fatigue on aerobic performance of handball athletes, as measured by the Yo-Yo IR1, and (2) explore possible alterations in heart rate regulation through HRR analysis. It was hypothesized that mental fatigue would impair physical performance, and alter the cardiac autonomic regulation of HR, respectively.

METHODS

Twelve regional-level handball players from an amateur club (age: 17.50 ± 3.63 years old; 5 ± 2.2 years of practice) participated in this randomized, cross-over investigation. As inclusion criteria, the participants should be affiliated to the state and/or national handball federation and should not present any injury in the last month. At the time of the study, all participants were competing in either state or national level events and trained an average of 6 hours per week. Prior to the study, the participants signed an informed consent form outlining the study

procedures which, in turn, were approved by leading authors' University Ethics Committee (project number 55286716.0.0000.5149).

Experimental Overview

Participants were instructed to maintain regular sleep patterns and consumption of caffeine. Furthermore, the participants were asked to avoid any vigorous exercise at least 24 h and take a regular meal at least 2 h before the testing sessions. The testing sessions were separated by a minimum of 72 h.

Upon arrival for testing, participants received a standard explanation of the procedures. Then, the participants received a standard explanation about the 6-20 RPE scale and were instructed to drink 500 mL of water. Subsequently, they were directed to a quiet room where the pre-assessment of mental fatigue was administered by (1) asking the participants to complete a Visual Analogue Scale (VAS); and (2) measuring five minutes of resting heart rate (HR) using a chest strap connected to a Polar V800 watch. Next, the control or mental fatigue treatment were conducted. Immediately following the treatment, the VAS scale was again completed. The participants were then directed to a handball court, whereby they completed the Yo-Yo Intermittent Recovery Test, level 1 (Yo-Yo IR1). No verbal encouragement was given to the participants during the tests. RPE was measured after every 40-m stage. After the test, the subjective assessments (i.e., RPE, Mental Fatigue and Mental Effort) were repeated and heart rate was recorded again during for 5 minutes.

Mental fatigue was induced using a 30-min paper version of a modified Stroop Color Word task. This test has been used in recent studies involving mental fatigue in sporting contexts.^{9,18} During the test, the participants verbalized the color of words (red, blue, green and yellow) printed in a random order. The correct answer corresponded to the ink color of the word. However, if the ink color of the word was "red", the correct answer was the word itself rather than the color of the word. A member of the research team monitored the participants' verbal responses. Upon making a mistake, the participants were instructed to restart the current line of words. Participants were instructed to respond correctly to as many words as possible. The control condition involved watching a 30-min emotionally neutral video involving the history of world aviation.

Perceptual Subjective Measures

Subjective ratings of mental fatigue, mental effort and motivation were recorded pre-treatment, post-treatment and post-running test using 100-mm VAS as a manipulation check. Motivation was measured only post-treatment, with respect to the upcoming running trial. This scale has been used in mental fatigue studies in sport and exercise.^{9,18} To analyze the VAS scales, a ruler was used to measure the distance between the initial mark and the point marked by the participant. Scores were reported as arbitrary units (AU).

Objective Performance Measures

The Yo-Yo IR1 test was performed according to the procedures suggested by.¹⁹ Test reliability was established in a previous study.²⁰ This test was validated to measure the aerobic performance in young

handball players.²¹ The Yo-Yo IR1 test consists of repeated 2 x 20-m runs back and forth between the starting, turning, and finishing line at a progressively increased speed controlled by audio bleeps from a tape recorder. Between each running bout, the participants were given a 10-s active rest period, consisting of 2 x 5 m of walking. When the subjects twice have failed to reach the finishing line in time, the distance covered was recorded as the final test result.

Blood lactate was measured as a manipulation check for the Yo-Yo IR1. Five microliters were taken from the fingertip before and immediately after the Yo-Yo IR1 test. Blood samples were stored at -80°C until analysis was performed and concentrations were determined using an electroenzymatic method (YSL 1500 SPORT, Yellow Springs, OH, EUA).

For the HRR measurement, conducted immediately following the Yo-Yo IR1, the participants remained lying down on the floor for five minutes, with a normal breathing rate, in silence and with no body movements. A chest strap (Polar® H7, Kempele, Finland) connected to a recording watch (Polar® V800, Kempele, Finland) was used to continuously recorded R-R intervals during this period (Task Force, 1996). All irregular heartbeats were replaced with interpolated adjacent R-R interval values using the Polar Software (Pro Trainer 5, Polar Electro, Finland). HR at the end of tests (HR_{end}) was defined as the HR registered at the exact moment in which the test ended. HRR assessment included the raw HR data, and was defined as the HR value at a given point within the recovery period (i.e., every 30 seconds). Relative HRR was defined as the difference between HR registered at the end of exercise (HR_{end}) and every 30s thereafter (i.e., Δ30s, Δ60s, Δ90s, Δ120s, Δ150s, Δ180s, Δ210s, Δ240s, Δ270s and Δ300s). This method of HRR analysis is in congruent with previous published empirical research guidelines in sport and exercise,^{15,22} and mirrored the protocol used in previous study.²³

Statistical Analysis

Data were initially examined for normality (Shapiro-Wilk test) and homogeneity (Levene's test). A paired Student's *t*-test was performed to compare mean data (collected at a single point) between the experimental trials. A series of two-way repeated measures ANOVAs followed by Tukey's *post hoc* tests were used to compare data between experimental trials over distance, or at different moments (PRE-TREAT, POST-TREAT and POST-RUN). A series of Wilcoxon Rank test (non-parametric tests) were used to compare RPE data between trials. Additionally, Cohen's *d* effect-size (ES) estimates were calculated to assess the magnitude of difference between the experimental conditions. ES was calculated through mean differences (Cohen, 1988) and was considered trivial (ES < 0.2), small (ES 0.2 – 0.6), medium (ES 0.6 – 1.2) or large (ES ≥ 1.2).²⁴ All analyses were performed in the Sigma Plot 11 statistical package. The significance level was set at $p \leq 0.05$.

RESULTS

Perceptual Subjective Measures

A significant condition x time interaction was found for subjective reports of mental fatigue ($F = 6.05$; $p < 0.01$; power = 0.77). Follow-up tests revealed no between-condition differences in mental fatigue at PRE-TREAT ($p = 0.76$; ES = 0.13). No differences were found over time analysis for control manipulation, between PRE-TREAT vs. POST-TREAT ($p = 0.95$; ES = 0.11) and POST-TREAT vs. POST-RUN ($p = 0.14$; ES = 0.57). In contrast, following the Stroop Test, mental fatigue increased ($p < 0.001$; ES = 1.36), and remained higher at POST-RUN ($p < 0.01$; ES = 1.13), compared to PRE-TREAT. A significant effect between experimental manipulations was found for POST-TREAT only ($p < 0.01$; ES = 1.32; see Figure 1-A).

Mental effort was higher than the control treatment after the Stroop Test ($p < 0.001$; ES = 2.80), but after exercise was not found different

between conditions ($p = 0.80$; ES = 0.08) (Figure 1-B). At POST-TREAT, motivation was not different between trials ($p = 0.28$; power = 0.08; ES = 0.29) (Figure 1-C).

A significant difference among the participants' RPE responses for the experimental condition was observed ($Z = -4.84$; $p > 0.001$) and RPE was higher in the mental fatigue condition over 80 – 200 m of Yo-Yo IR1, and reached similar values close to the 40-m mark at the end of both conditions (Figure 2-A).

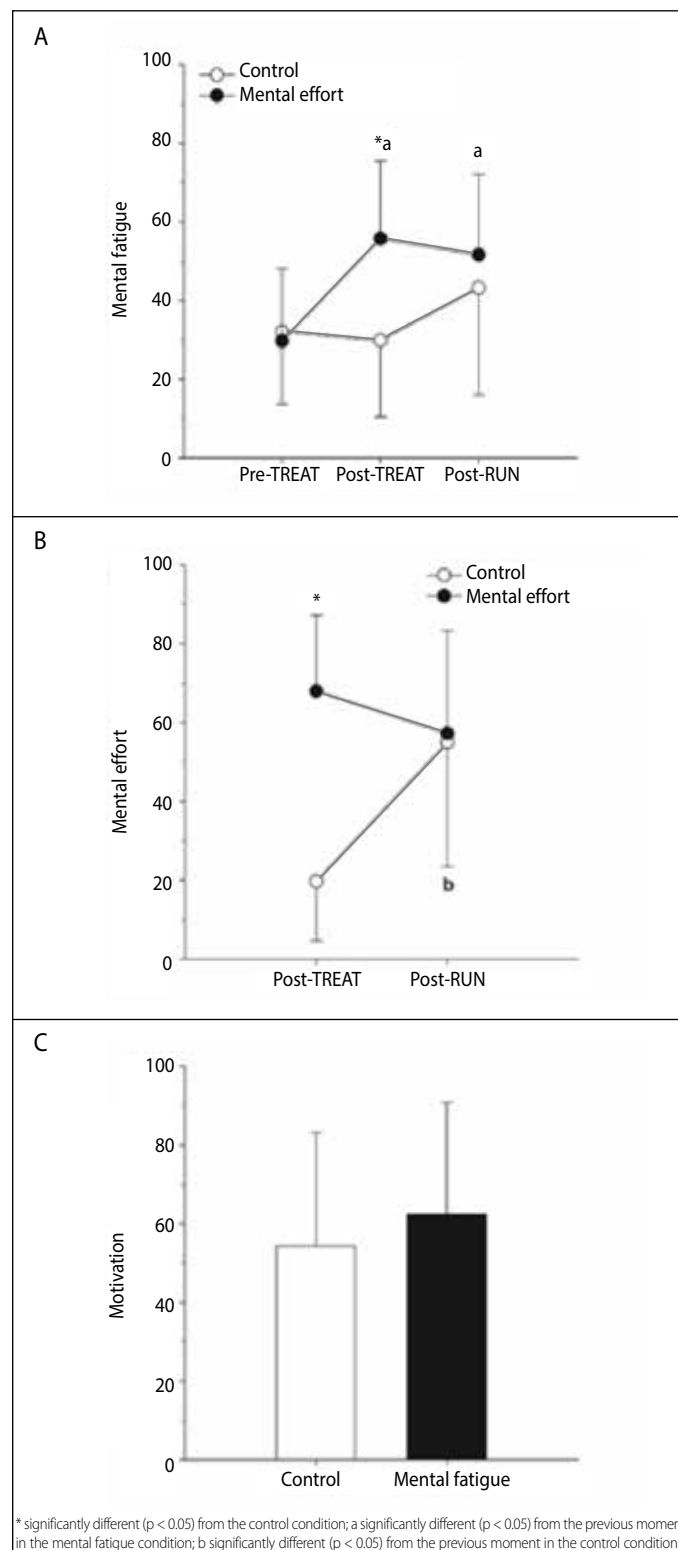

Figure 1. Subjective measures of mental fatigue (A) before (PRE-TREAT), after the Stroop test or control manipulation (POST-TREAT) and at post-running (POST-RUN). Mental effort (B) after the Stroop test or control manipulation (POST-TREAT) and at post-running (POST-RUN). Motivation (C) before the running time-trial for both conditions.

Figure 2. Rate of perceived exertion (A) and blood lactate values (B) during running the Yo-Yo IR1 time-trial for both experimental conditions.

Objective Performance Measures

The mental fatigue manipulation reduced the total distance covered during the Yo-Yo IR1 ($7.9 \pm 10.4\%$; $p < 0.05$; power = 0.68; ES = 0.40; see Figure 3-A). Overall, 10 of the 12 handball players ran a shorter distance in YO-YO IR1 after being subjected to the Stroop task (Figure 3-B).

Blood lactate levels increased after running Yo-Yo IR1 at POST-RUN ($p < 0.01$; ES = 4.95). However, blood lactate responses only showed a significant effect for the time of analysis; i.e., pre-to post ($F = 113.89$; $p > 0.001$; power = 1.00). No significant differences between experimental conditions was observed ($F = 0.15$; $p = 0.71$; power = 0.05).

No significant differences in HRR were observed between conditions (Figure 4).

DISCUSSION

In the present study, we tested the hypotheses that a mental fatigue state would: (1) impair aerobic performance; and (2) alter HRR values after a Yo-Yo IR1 test among handball athletes. Our findings confirmed the first hypothesis only. Specifically, mentally fatigued subjects showed an impaired running performance without any concomitant changes in their HRR or blood lactate concentrations. Collectively, these findings corroborate previous studies on the relationship between mental fatigue and physical performance.^{8,9,18}

Regarding the subjective perceptual measures analyzed, our findings indicate that a 30 min Stroop task induced a mental fatigue state (Figure 1-A). Specifically, perception of mental fatigue, as measured by the VAS,

Figure 3. Mean total distances (A) and individual distances (B) covered at Yo-Yo IR1 time-trial at the two-experimental condition (i.e., control and mental fatigue trials).

Figure 4. Heart Rate Recovery values after the Yo-Yo IR1 for both experimental conditions.

was higher in the mentally fatiguing condition when compared to control. The same pattern was observed for perceived mental effort (Figure 1-B). Together, these findings indicate that the participants in the mentally fatiguing condition started the running test under a higher cognitive stress which, in turn, might explain their decreased physical performance. Importantly, decreased physical performance in the experimental condition was not due to motivation, as perceived motivation scores

did not differ between conditions (Figure 1-C). In this regard, mental fatigue has been associated with impairment in other affective factors, such as efficiency and availability of resources, but has not been shown to affect motivation²⁵.

The results concerning RPE revealed a higher perception of effort in the mentally fatiguing condition (Figure 2-A). This result corroborates other investigations that have shown an increased RPE trend in a mentally fatigued condition given two identical exercise protocols.⁸ These findings demonstrate that cognitively demanding activity before exercise is harmful to performance, especially when effort regulation is required, since no influence was identified in all-out tests when individuals were mentally fatigued.²⁶

The analysis of the Yo-Yo IR1 running test results demonstrated that physical performance in handball athletes was negatively affected by the mental fatigue (Figure 2). These results corroborate previous findings in intermittent exercise in general,⁹ and interactive team sports in particular.¹⁸ In the case of handball, which is a sport that requires intermittent efforts (physical demand), multiple tactical decisions and prolonged sustained attention (mental demand), long term-training of both demands could increase resilience to mental fatigue.²⁷ In the present study, this putative resilience effect to mental fatigue was not identified; the participants were sensitive to mental fatigue (Figure 1-A), which in turn led to impaired physical performance (Figure 2). This contrast is likely due to differences in performance level of the athletes.

Regarding the physiological markers of performance, no differences between conditions were observed in blood lactate concentration (Figure 2-B) and in the HRR (Figure 4). Hence, similar to the observed by,⁹ the impaired intermittent running performance of handball players presented by the mentally fatigued condition cannot be explained by

any cardiometabolic alteration. Again, only perceptual changes related to the effort employed in the Yo-Yo IR1 running test were observed.

It follows that our hypothesis that mental fatigue alters the vagal tonus and promotes sympathetic hyperactivity was not supported. It is well established that the HRR is modulated mainly by parasympathetic reactivation and sympathetic withdrawal after the cessation of cardiovascular exercise.²⁸ Despite some studies showing that mental fatigue protocols can lead to an altered autonomic activity (measured by heart rate variability),¹² it seems that a 30 min Stroop color test is not enough to alter this autonomic balance after an intermittent running test using HRR as a parameter. This difference is not marginal as HRR and heart rate variability are related to separate mechanisms within the autonomic system. Heart Rate Variability reflects the parasympathetic modulation, whereas HRR is preferentially related to vagal tonus.²² Hence, the present study suggests that mental fatigue does not influence recovery of the vagal tonus after intermittent exercise, which thereby can present different kinetics when compared to continuous exercise.²⁹

CONCLUSIONS

The present study demonstrates that induction of mental fatigue impaired physical performance in handball players subjected to a Yo-Yo IR1 test. During the mentally fatigued condition, athletes presented a higher RPE, and ran shorter distances than in the control condition. No changes in HRR were observed between conditions. In practice, our results suggest the importance of avoiding any activity involving higher cognitive demands prior to important training sessions and matches due to their potential harmful effects on exercise endurance.
