27 **Abstract**

28 The present study aimed to assess the differences in pre-season knee strength asymmetries, flexibility,
29 and aerobic capacity of soccer players that sustained lower-body injuries during the in-season period
30 compared to those that did not have a lower-body injury. A secondary purpose was to compare the
31 aforementioned parameters between the players that sustained a knee ligament injury and hamstring
32 strain. One hundred and thirty-three division 1 soccer players participated in the study. Fitness testing
33 was conducted at the end of the pre-season period, and the players were followed for a total of 20 games.
34 The anthropometric, lower body strength, flexibility and aerobic capacity parameters were compared
35 between the players that sustained hamstring strains and knee ligament injuries and those that did not
36 sustain any injuries. Results indicated that injured players were significantly older and less flexible than
37 non-injured players ($p<0.05$). Additionally, injured players appeared significantly weaker on the right
38 and left quadriceps and hamstring muscles ($p<0.05$). Furthermore, injured players had significantly
39 greater asymmetries for the hamstrings muscle ($p<0.05$) and significantly lower VO₂max values and
40 running time than the non-injured players ($p<0.05$). Lastly, a significant difference between the players
41 that sustained a hamstring injury compared to those who sustained a knee injury was indicated in right
42 hamstring strength, right side ratio, and hamstring asymmetries ($p<0.05$). Our findings suggest that off-
43 and pre-season interventions should be tailored toward increasing aerobic fitness and lower body
44 strength and flexibility while minimizing strength asymmetries and imbalances to reduce in-season
45 injury risk.

47

48

49 **Introduction**

50 Professional soccer is generally known to be associated with a relatively high injury rate
51 (Hawkins, Hulse, Wilkinson, Hodson, & Gibson, 2001). Research indicated that the total injury
52 incidence in professional soccer players ranges from 2.48 (Ekstrand, Hagglund & Walden, 2011) to 9.4
53 injuries per 1000 hours of exposure (Walden, Hagglund, & Ekstrand, 2005). More specifically, the
54 injury rate during competition ranges from 8.7 to 65.9 injuries per 1000 hours of exposure, whereas the
55 injury incidence during training is between 1.37 to 5.8 injuries per 1000 hours of exposure (Ekstrand,
56 Hagglund, & Walden, 2011, Eirale, Hamilton, Bisciotti, Grantham & Chalabi, 2012). Furthermore, an
57 analysis of 6030 injuries in soccer players indicated that the majority of injuries were classified as strains
58 (37%) and sprains (19%), with the lower extremity being the site of 87% of the reported injuries
59 (Hawkins, Hulse, Wilkinson, Hodson, & Gibson, 2001). Additionally, research affirmed that soccer
60 injuries are associated with the players' age, exercise load, professional level, and pre-season training
61 status (Dauty & Collon, 2011; Clemente et al., 2017a; Clemente et al., 2017b; Eliakim, Doron, Meckel,
62 Nemet, & Eliakim, 2018; Nobari et al., 2021).

63 It is imperative to identify the modifiable risk factors in order to prevent time-loss due to soccer-
64 related injuries and maintain soccer players' health and safety. For over a decade, investigators have
65 examined the effect of specific factors on fatigue (Clemente et al., 2017a; Clemente et al., 2017b; Nobari
66 et al., 2021; Nobari, Fani, Pardos-Mainer, & Pérez-Gómez, 2021) and soccer-related injuries with an
67 ultimate goal to prevent them. In this regard, it is debatable whether it is possible to use screening tests
68 to determine who is at an increased risk for a sports injury. Nonetheless, research indicated that a
69 combination of tests during the pre-season period that identify bilateral and ipsilateral isokinetic
70 asymmetries and mixed ratios could potentially predict the likelihood of hamstring injury in
71 professional soccer players during the competitive season (Dauty, Menu, Fouasson-Chailloux, Ferréol,
72 & Dubois, 2016). Furthermore, it was demonstrated that lower pre-season isokinetic hamstring strength
73 and a lower hamstring-to-quadriceps ratio increase the risk of acute hamstring strain injury during the
74 in-season period (Lee, Mok, Chan, Yung, & Chan, 2018). Concurrently, if the asymmetry between the
75 knee extensors exceeds 10%, it increases the risk of musculoskeletal injuries by 16 times and ligament
76 and meniscus injuries by up to 28 times (Liporaci, Saad, Grossi, & Riberto, 2019). Moreover, if a

77 strength imbalance is over 10% in the knee flexors, the risk of injury increases by 12 times. Notably,
78 soccer players have shown differences in strength and flexibility between the dominant and non-
79 dominant limbs, which may be due to the technical elements that involve one-sided activities such as
80 kicking, tackling and passing, performed during the games and training (Rahnama, Lees, &
81 Bambaecichi, 2005). Research also indicated that long-term participation in soccer leads to the
82 development of various degrees and modes of functional asymmetry (Fousekis, Tsepis, & Vagenas,
83 2010). While the aforementioned studies indicated an association between the forces generated at slow
84 isokinetic speeds and lower limb injury incidence, slow-velocity strength production alone might not
85 fully represent the forces generated during a soccer game. Notwithstanding, the rationale for assessing
86 lower-body isokinetic strength and imbalances remains, although it must be acknowledged that the risk
87 of injury is multi-factorial (Hughes, Sergeant, Parkes, & Callaghan, 2017).

88 In addition to the aforementioned factors, studies in various groups indicated that aerobic fitness
89 might be a recognized risk factor for injury (Watson, Brickson, Brooks, & Dunn, 2017; Eliakim, Doron,
90 Meckel, Nemet, & Eliakim, 2018). Research on female teenage soccer players demonstrated that a
91 higher level of pre-season aerobic fitness is related to a lower risk of injury and sickness throughout the
92 season, suggesting that the off-season training program should be tailored towards increasing aerobic
93 fitness, which may aid in injury and illness prevention (Watson, Brickson, Brooks, & Dunn, 2017).
94 Additionally, research indicated that improvements in VO₂ max during the pre-season training period
95 were significantly lower among injured soccer players than non-injured players, while the fitness
96 characteristics at the beginning of pre-season training were not significantly different between the two
97 groups (Eliakim, Doron, Meckel, Nemet, & Eliakim, 2018).

98 Pre-season soccer training aims to prepare the players mentally and physically to withstand the
99 demands associated with the training and competition during the in-season. Unlike other sports, soccer
100 is characterized by a shorter pre-season training period and a longer in-season period, especially when
101 teams participate in international games (Francioni et al., 2016). Thus, the pre-season period is
102 characterized by a high training load compared to the in-season period (Francioni et al., 2016).
103 Therefore, a careful strategic periodization is required for the players to increase their aerobic capacity
104 and strength and reduce possible asymmetries, which may result in injuries during the in-season period.

105 The present study aimed to assess the differences in pre-season intra- and inter-limb strength knee
106 asymmetry, flexibility, and aerobic capacity of soccer players that sustained lower-body non-contact
107 injuries during the in-season period compared to those that did not have a lower-body injury. The study's
108 secondary purpose was to compare the aforementioned parameters between the players that sustained a
109 knee ligament injury and hamstring strain.

110

111 **Methods**

112 *Participants*

113 A total of one hundred and thirty-three division 1 soccer players ($n=133$, age 25.51 ± 5.59 years,
114 height 179.9 ± 17 cm) participated in the study. Fitness testing was conducted at the end of the pre-season
115 period, and the players were followed for a total of 20 games (from Aug 20, 2021, to Feb 5, 2022). The
116 initial sample included 155 players, but only 133 met the inclusion criteria. Players diagnosed with
117 COVID-19 within two months before the collection of data were excluded from the study. Furthermore,
118 players with a previous lower-body injury within the last six months or those that had an injury during
119 the pre-season training period were excluded from the study. Additionally, players with contact injuries
120 or injuries other than hamstring strains (grade 2 and up) and knee ligament injuries were also excluded.
121 The injuries were included only when they were clinically diagnosed and resulted in an absence from
122 training or competition of at least seven days. Only injuries classified as moderate (8–28 days of
123 absence) and major (more than 28 days of absence) were included in this study (Hägglund, Waldén,
124 Bahr, & Ekstrand, 2005). Therefore, the study included the players that sustained hamstring strains
125 (grade 2 and up) and knee ligament injuries and those that did not sustain any injuries. Participants and
126 the medical team of the five participating teams were asked to report any injury that occurred during a
127 soccer game or training and resulted in the athletes' inability to continue participating. In addition, they
128 were asked to provide the date of the injury, the body part involved, and the mechanism.

129

130 *Procedures and data collection*

131 Players were advised to abstain from any activity the days before testing, and measurements
132 were obtained between 9:00 am and 14:00 on two different days to avoid potential fatigue from

133 subsequent testing. Testing was part of the professional team's seasonal plan to examine the players'
134 readiness at the end of the pre-season period, but players' participation in this study was completely
135 voluntary. Each player was briefed on the procedures and signed an informed consent before data
136 collection. Ethical guidelines were followed according to the Helsinki Declaration's ethical standards,
137 and the University's ethics committee board (reference number STEMH 541) approved the study.

138

139 *Anthropometric measurements*

140 A wall stadiometer (Leicester; Tanita, Japan) was used to measure the players' stature, while a
141 leg-to-leg bioelectrical impedance analyzer (BC418MA; Tanita) was utilized to measure body
142 composition. Before the measurements were obtained, all players were instructed to follow the standard
143 BIA (bioelectrical impedance analysis) guidelines (Kyle et al., 2004).

144

145 *Sit and reach test*

146 A sit and reach box was used to assess the flexibility of the lower back and hamstring muscles
147 according to methods described by previous investigators (Russell, 1980). Players removed their shoes
148 and placed the soles of their feet against the box while their knees were fully extended. They were
149 instructed to avoid fast and jerky movements while leaning forward with their hands on top of each other
150 and palms facing downwards. They performed two practice trials, and the third trial was recorded to the
151 nearest cm.

152

153 *Lower body strength*

154 The isokinetic knee strength was assessed utilizing the Humac Norm and Rehabilitation device
155 (CSMI, Stoughton, MA, USA) according to the methods described by previous investigators (Parpa &
156 Michaelides, 2020). Before the isokinetic testing, players had a 5-min self-paced warm-up on a
157 mechanically braked cycle ergometer (Monark 894 E Peak Bike, Weight Ergometer, Sweden). Once the
158 players were appropriately positioned on the device, they performed five sub-maximal repetitions of
159 concentric knee flexion and extension for familiarization purposes. The isokinetic testing included three
160 maximal concentric flexion and extension repetitions at an angle speed of 60°/sec.

161

162 *Cardiopulmonary exercise testing*

163 The players completed an incremental maximal cardiopulmonary exercise testing until they
164 reached exhaustion on a treadmill (h/p/Cosmos Quasar med, H-P-Cosmos Sports & Medical GmbH,
165 Nussdorf-Traunstein, Germany). The players were tested utilizing the modified Heck incremental
166 maximal protocol, which was previously validated for its reliability to test soccer players (Santos-Silva,
167 Fonseca, Castro, & Greve, 2007; Parpa & Michaelides, 2022). A breath-by-breath analysis was
168 performed on the Cosmed Quark CPET (Rome, Italy) system while laboratory conditions were kept
169 constant (temperature $22\pm 1^\circ\text{C}$ and relative humidity at 50%). The test came to an end when the
170 participant reached volitional fatigue or when there was no variation among the VO_2 levels while the
171 workload increased. The $\text{VO}_{2\text{max}}$ was detected following filtering the results to identify the highest
172 value for an average of 10 seconds. The ventilatory threshold and respiratory compensation point were
173 determined using different criteria. The ventilatory threshold was determined through the V-Slope
174 method and was verified at the nadir of the $\text{VE}/\dot{V}\text{O}_2$ curve. The respiratory compensation point was
175 determined at the nadir of the $\text{VE}/\dot{V}\text{CO}_2$ curve.

176

177 *Statistics*

178 SPSS 26.0 for Windows (SPSS Inc., Chicago) was utilized to analyze the results. The
179 homogeneity of variance and normality assumptions were verified using Brown and Forsythe's and
180 Shapiro-Wilk tests, respectively. Means and Standard Deviations were calculated for all the parameters.
181 Means were compared using an independent samples t-test. Cohen's d was calculated to determine the
182 effect size. Effect sizes were interpreted as small (0.2-0.4), medium (0.5-0.7) and large (0.8-1.4) (Cohen,
183 1988). For the statistical analyses, significance was accepted at $p < 0.05$.

184

185

186

187 **Results**

188 The anthropometric and body composition parameters are presented in table 1. Following the
 189 twenty in-season games, 37 players suffered either a hamstring strain (n=20) or knee ligament injury
 190 (n=17).

191 **Table 1.** Demographic Characteristics of injured and non-injured players.

192 Note.*p<0.05; CI: confidence interval

	Injured		Non-Injured		95% CI for the difference	
	n	Mean±SD	n	Mean±SD	Lower	Upper
Age (years)	37	27.08±6.32*	96	24.91±5.19	-4.29-(-0.062)	
Height (cm)	37	175.02±29.98*	96	181.79±6.94	0.34-13.20

Fat % BIA	37	10.61±3.32	96	10.57±2.94	-1.21-1.13	

193 It should be noted that 16 out of the 20 hamstring injuries and 14 out of the 17 knee ligament
 194 injuries occurred during a competitive game. Results indicated that injured players were significantly
 195 older [t(131)=-2.036, d= 0.375, p<0.05], while at the same time, they were significantly shorter [t(131)=-
 196 2.084, d=0.32, p<0.05] and lighter than non-injured players [t(131)=-2.59, d=0.51, p<0.05] (Table 1).

Hamstrings asymmetry	37	10.43±7.14*	96	5.53±4.18	-6.88-(-2.92)	

210 Furthermore, the examination of flexibility indicated that injured players were significantly less
 211 flexible [$t(131)=-4.79$, $d=0.85$, $p<0.05$] than non-injured players (Table 2). Additionally, considering
 212 lower body strength parameters, injured players appeared to be significantly weaker on both right and
 213 left quadriceps and hamstring muscles ($p<0.05$) compared to non-injured (Table 2, Figure 1).

214

219

220

221

222

Figure 1. Lower body strength of injured and non-injured players

223

224 Note * $p < 0.05$

225 Considering muscle asymmetries, injured players had significantly [$t(131) = 4.90$, $d = 0.84$,
 226 $p < 0.05$] greater bilateral difference for the hamstrings muscle compared to non-injured players (Table
 227 2). Furthermore, results indicated significantly lower VO_{2max} values [$t(131) = 4.64$, $d = 0.95$, $p < 0.05$]
 228 and running time [$t(131) = 5.44$, $d = 1.07$, $p < 0.05$] for the injured players compared to the non-injured
 229 players (Table 3, Figure 2). Concurrently, VO_2 values at ventilatory (VT) threshold [$t(131) = 2.43$,
 230 $p < 0.05$] and respiratory compensation point (RC) [$t(131) = 3.85$, $p < 0.05$] were significantly lower for
 231 the injured players (Table 3).

232 **Table 3.** Aerobic capacity of injured and non-injured players.

	Injured		Non-Injured		95% CI for the difference	
	n	Mean±SD	n	Mean	Lower	Upper
VO_{2max} (ml/kg/min)	37	53.77±3.24*	96	57.46±4.39	2.12-5.26	
Running time (min)	37	15.84±1.51*	96	17.55±1.68	1.09-2.34	

VO2 at VT (ml/kg/min)	37	37.91±3.88*	96	40.49±5.97	0.83-4.33	233 234
VO2 at RC (ml/kg/min)	37	47.04±5.08*	96	50.56±4.59	1.71-5.33	235 236

237 Note. *p<0.05; CI: confidence interval; VO2max: maximal oxygen uptake; VO2 at VT: oxygen

239

240 **Figure 2.** Oxygen consumption at ventilatory threshold (VO2 at VT), at respiratory compensation
241 point (VO2 at RC) and VO2max of injured and non-injured players

242

243 Note *p<0.05

244 Concerning the aforementioned parameters based on the type of the injury, results indicated that
245 the players who sustained hamstring injuries were not significantly different in aerobic performance,
246 flexibility or anthropometric characteristics compared to those that sustained a knee injury. On the
247 contrary, a significant difference between the two groups was indicated in right hamstring strength
248 [t(35)=2.92, p<0.05], right side ratio [t(35)=4.43, p<0.05], and hamstring asymmetries [t(35)=-2.73,
249 p<0.05]. A borderline significant difference was also indicated in the left hamstring strength between
250 the two groups [t(35)=1.96, p=0.07]. More specifically, hamstring asymmetry was 13.13±7.6 for the
251 players that sustained a hamstring injury, while it was 7.24±5.09 for the players that sustained a knee
252 ligament injury. Furthermore, players who sustained a hamstring injury had significantly weaker right

253 hamstring muscles (152.60 ± 24.70 Nm) than those who sustained a knee ligament injury (174.53 ± 20.20
254 Nm).

255

256 **Discussion**

257 The present study aimed to examine the differences in pre-season intra- and inter-limb strength
258 knee asymmetry, flexibility, and aerobic capacity of soccer players that sustained lower-body non-
259 contact injuries during the in-season period compared to those that did not have any lower-body injuries.
260 After twenty in-season games, twenty players suffered a hamstring strain, and seventeen players suffered
261 a non-contact knee ligament injury. Results indicated that injured players were significantly older and
262 less flexible than non-injured players. Additionally, injured players appeared to be significantly weaker
263 on both right and left quadriceps and hamstring muscles and had greater bilateral differences for the
264 hamstrings muscle than non-injured players. Furthermore, results indicated significantly lower VO₂max
265 values and running time for the injured players than for non-injured players. Lastly, the players who
266 sustained a hamstring injury were significantly weaker on the hamstring muscles and had significantly
267 greater hamstring asymmetries than those who sustained a knee ligament injury. Whilst these results
268 should not be a surprise, these data clearly show that injured players were significantly weaker, had
269 greater imbalances and had significantly lower physical fitness and flexibility at the beginning of the
270 season, which might have contributed to the development of lower-body injuries.

271 The role of muscle strength, imbalances and flexibility are particularly interesting because these
272 are modifiable risk factors and potential points of engagement for hamstring injury prevention. Research
273 indicated that a mixed ratio of less than 0.8, an ipsilateral ratio of less than 0.47, and a bilateral ratio of
274 less than 0.85 were the most predictive of a hamstring injury (Dauty, Menu, Fouasson-Chailloux,
275 Ferréol, & Dubois, 2016). In addition, the ipsilateral ratio of less than 0.47 allowed the prediction of the
276 severity of the hamstring injury (Dauty, Menu, Fouasson-Chailloux, Ferréol, & Dubois, 2016). In our
277 study, the ratios of injured and non-injured players were within normal values and did not indicate any
278 risk when the injured players were analyzed as one group. However, when the players were compared
279 based on the type of injury they sustained, it was demonstrated that those who sustained a hamstring
280 injury had a mean ratio of 68, while those who sustained a knee ligament injury had a mean ratio 82.94.

281 This finding supports that those ratios may be predictive of a hamstring injury, as indicated by other
282 research as well (Lee, Mok, Chan, Yung, & Chan, 2018), rather than a knee ligament injury.
283 Furthermore, the hamstring asymmetry of the injured group was over 10% which is in agreement with
284 other studies (Liporaci, Saad, Grossi, & Riberto, 2019). More specifically, research demonstrated that a
285 strength imbalance of over 10% in the knee flexors increases the risk of injury by 12 times (Liporaci,
286 Saad, Grossi, & Riberto, 2019). In our study, when the injured players were analyzed based on the injury
287 they sustained, it was indicated that hamstring asymmetry was 13.13 ± 7.6 for the players that sustained
288 a hamstring injury, while it was 7.24 ± 5.09 for the players who sustained a knee ligament injury. This
289 finding further supports that hamstring imbalances of over 10% may predict hamstring injuries rather
290 than knee ligament injuries. On the contrary, other studies (Izovska et al., 2019) suggested that those
291 imbalances in the flexors of the knee may predominantly be associated with the rupture of the anterior
292 cruciate ligament and other parts of the knee. Of note is that no strength asymmetry between the knee
293 extensors was presented in the injured and non-injured group.

294 Considering lower body strength and flexibility, our results align with other studies indicating
295 that lower pre-season isokinetic hamstring strength increases the risk of acute hamstring strain injury
296 during the in-season period (Wan, Qu, Garrett, Liu, & Yu, 2017). Our results demonstrated that injured
297 players were significantly weaker in the quadriceps and hamstring muscles than non-injured players.
298 Furthermore, while no significant differences were demonstrated between the players who sustained
299 hamstring injuries and knee ligament injuries in the strength of the quadriceps, the hamstring injured
300 group had significantly weaker right hamstring muscles (152.60 ± 24.70 Nm) compared to those that
301 sustained a knee ligament injury (174.53 ± 20.20 Nm). Concurrently, our findings indicated that injured
302 players had significantly lower flexibility assessed by the sit and reach test than non-injured players.
303 Flexibility was not significantly different among the players that sustained a hamstring injury or knee
304 ligament injury. These results align with previous investigators who indicated that in sports that involve
305 sprinting, athletes with good hamstring flexibility have lower peak hamstring muscle strains than
306 athletes with poor hamstring flexibility. In contrast, other studies suggest that hamstring flexibility
307 cannot be used to predict a hamstring injury accurately (Gabbe, Finch, Bennell, & Wajswelner, 2005).
308 Notably, there is conflicting evidence that older age, increased quadriceps peak torque, hamstring

309 flexibility and strength imbalances increase the risk of a hamstring injury (Freckleton & Pizzari, 2013).
310 The differences in the methodology utilized by the different studies might have contributed to these
311 conflicting results. Nevertheless, lower hamstring flexibility should not be ignored as it may turn into a
312 risk factor, especially when combined with other risk factors such as strength and asymmetries.

313 In addition to the aforementioned risk factors, research affirms that aerobic fitness might be a
314 recognized risk factor for injury (Watson, Brickson, Brooks, & Dunn, 2017; Eliakim, Doron, Meckel,
315 Nemet, & Eliakim, 2018). Our results indicated that injured players had significantly lower VO₂max
316 values and running time on the treadmill than the non-injured players. Concurrently, the injured players'
317 VO₂ values at the ventilatory threshold and respiratory compensation point were significantly lower.
318 These results are in agreement with previous studies that demonstrated a negative association between
319 pre-season aerobic fitness and injury risk throughout the season (Watson, Brickson, Brooks, & Dunn,
320 2017). In addition, research indicated that lower improvements in VO₂max during the pre-season
321 training are associated with higher injury rates during the in-season period (Eliakim, Doron, Meckel,
322 Nemet, & Eliakim, 2018).

323 To our knowledge, this is the first study that evaluated lower body strength, asymmetries,
324 flexibility and aerobic performance as risk factors for injuries in soccer players. Together, our findings
325 suggest that off, and pre-season interventions should be tailored toward increasing aerobic fitness, lower
326 body strength and flexibility while minimizing strength asymmetries and imbalances (especially in the
327 hamstring muscles) in order to reduce in-season injury risk.

328

329 *Limitations*

330 Despite the significant findings, this study comes with several limitations. First, the injuries
331 were not specified based on the players' playing position, which could be linked with different muscle
332 strength profiles. Furthermore, hamstring injuries should have been separated into the stretch-type and
333 sprint-type hamstring injuries. In addition, extrinsic factors such as the quality of the soccer field,
334 insufficient warm-up, and differences in the training load of the participating teams could not be
335 controlled.
