FIELD AND LABORATORY STUDIES OF THE EARTHWORM *Dendrobaena alpina* (Rosa, 1884)

Abstract: Distribution of *Dendrobaena alpina* covers the mountainous region of central Europe, where it has a high dominance and frequency index. This work describes data from field studies conducted over two annual cycles in the Bieszczady National Park (BNP), Poland, in different types of beech forest. Densities of this species ranged from 47-231 · m⁻² with associated biomasses of 19 – 90 g · m⁻². Most (66 %) were recovered from less than 0.1 m soil depth with a further 28 % to 0.2 m. Further animals were collected alive from Lutowska close to the BNP to obtain baseline data on the life history of *D. alpina*. Mature individuals were kept in isolation and cocoon production monitored on a 2 monthly basis. Immature individuals were kept until they reached maturity, when they were paired, with combined output of cocoons regularly monitored. Cocoons were collected, had masses determined and were incubated. Hatchability was recorded, as was estimated duration of incubation and growth to maturity. Field-collected adults had a mean mass of 1.4 g and at 15°C, these produced an average of 1.83 cocoons worm⁻¹ · month⁻¹. Zero cocoons were produced by further specimens, collected as immature, grown to maturity and maintained in isolation. Recently-matured, paired *D. alpina* produced an average of 1.65 cocoons worm⁻¹ · month⁻¹. Cocoons had a mean mass of 19 mg. At 15°C, cocoons produced by recently matured adults hatched after 80 days (82 % viable), but after 2 months the majority of cocoons failed to hatch. Hatchling growth from an average of 18 mg to maturity required 7-11 months in the given substrate.

Key words: Earthworms, Ecology, Field study, Laboratory culture, Poland, Population dynamics

Introduction

Dendrobaena alpina (Rosa, 1884) (Annelida/ Clitellata/ Oligochaeta/ Lumbricidae) occurs in the Alps, the Southern Carpathians and Balkans (CSUZDI et al. 2005). It is characterised by a cylindrical body shape (length 40-120 cm with 65-155 segments). The species is variable in colour, ranging from violet to bright red dorsally and rosy-tinged beige ventrally. It has an epilobic prostomium and distantly spaced chaetae. The clitellum is present across segments 28-33 (PLISKO 1973, KASPRZAK 1986). In the field it is easily recognized among other similarly coloured earthworm species by its violent escape response. Previous studies in Poland within the Bieszczady National Park (BNP), SE Poland (KOSTECKA & SKOCZEŃ 1993), have shown associations of *D. alpina* with *Allolobophora carpathica* (Cognetti, 1927), *Allolobophora cernovitoviana* (Zicsi, 1967) and *Aporrectodea rosea* (Savigny, 1826). Field sampling in beech woodlands within the BNP, found *D. alpina* in soils with a pH of 3.3 - 5.0 and C:N ratios around 13:1 (KOSTECKA & SKOCZEŃ 1993).

This paper combines unpublished data from field sampling over two field seasons with controlled laboratory investigations to rear of *D. alpina*. The aims were to obtain fundamental information on population dynamics and specific data on aspects of life history of this species.

Methods

Field sampling

Work was conducted in four areas of Carpathian beech (*Fagetum carpathicum*) woodland

¹ University of Rzeszow, Faculty of Agriculture and Biology, ul. Ćwiklińskiej 2, 35-959, Rzeszów, Poland

within the BNP in the vicinity of Ustrzyki Górne in the years of 1986-1987 (unpublished data). Each of the four sites (sub-assemblies of the beech woodland) was classified according to a homogenous ground flora community cover: 1 - *F. c. festucetosum drymejae*; 2 - *F. c. typicum*; 3 - *F. c. lunarietosum*; 4 - *F. c. allietosum*. Sampling, over two field years was during the months of May to November, when access to field sites is possible. Within each site and on all occasions, 5 samples were taken. Soil blocks 0.25 x 0.25 x 0.2 m were dug out and the soil inspected by hand sorting, with specimens from deeper layers extracted with a 0.4 % formalin solution (RAW 1959, ZAJONC 1970). Collected specimens were preserved in 4 % formalin in the field for later identification (PLISKO 1971, KASPRZAK 1986). The relative contribution of *D. alpina* (fot. 1) to the total earthworm community at each site was determined. Mean densities and masses for *D. alpina* at the given sampling sites were also calculated. Earthworms densities between sites were compared using ANOVA with a post hoc HSD Tukey's test (SOKAL & ROHLF 1981).

Laboratory monitoring

In June 2008, live specimens of *D. alpina* were collected by digging and hand-sorting of soil, from beech-dominated forest soils near Lutowiska (N 49° 17.11' E 22° 40.91') close to the BNP. These mature and immature animals (n=36) were transported to the laboratory in native soils for examination of life history traits. To obtain maximum data, animals were treated as described by BUTT & GRIGOROPOULOU (2010). Initially each was examined, identified as closely as possible, had stage of development and mass recorded. Each was then individually housed in a 0.4 dm³ plastic container with a small proportion of native soil supplemented with Kettering loam and surface fed with dried and re-wetted horse manure (LOWE & BUTT 2005). These animals were maintained at 15°C in temperature-controlled chambers and initially monitored on a monthly basis. Masses were recorded and if clitellate at time of collection, the soil in which the earthworm was kept was wet-sieved for cocoons (sieves of 4.0, 2.8 and 2.0 mm). Thereafter, fresh Kettering loam and food was provisioned. Immature animals were maintained in isolation until maturity was reached and then for 2 months beyond this. After maturation the soil in which these animals were kept was also wet-sieved to check for any cocoon production from unmated individuals. After this, *D. alpina* that had matured in the laboratory were put together (n=9 pairs) in 0.4 dm³ containers and sampled monthly for cocoons over a period of 15 months as previously described.

Collected cocoons were placed on moistened filter papers within 9 cm diameter Petri dishes at 15°C, after cocoon masses (blotted dry) were recorded. Cocoons were monitored on a regular basis and date of hatching success, number of hatchlings emerging and hatchling masses were recorded. Length of incubation was calculated as time required to hatch after collection plus half of the elapsed time since previous cocoon collection. Selected hatchlings were monitored for growth. Individuals (n=10) were kept in 0.4 dm³ containers with a substrate of Kettering loam mixed with processed horse manure. These were monitored on a monthly basis over a period of 8 months.

Results

Field data showed *D. alpina* to be present at all of the sampled sites. Figures 1a and 1b show recorded densities and biomasses, respectively over the sampling period. Of 13 earthworm species collected, *D. alpina* was one of only three to occur in large numbers at all sites investigated along with *A. cernovitoviana* and *A. carpathica*. Chosen attributes of *D. alpina* from the four field sites are provided in Table 1. The density of *D. alpina* at *Fagetum carpathicum allietosum* differed significantly from that at the other sites ($p < 0.05$).

The majority (66 %) of *D. alpina* were collected from soil depths of less than 0.1 m, with a further 28 % to 0.2 m. During October and November sampling numbers obtained from hand-sorting at all sites were much lower in the upper levels than earlier in the year, due to the earthworms descending deeper into the soil and entering a resting state, where they protect themselves against adverse environmental conditions and do not react to extraction from deeper soil layers.

Fig. 1. Dynamics of *Dendrobaena alpina* density (a) and biomass (b) at four differing sites of *Fagetum carpathicum* near Ustrzyki Górne over 2 sampling years
 Sites presented from the left as: *Fagetum carpathicum festucetosum* (site I); *F.c. typicum* (site II); *F.c. lunarietosum* (site III); *F.c. allietosum* (site IV)

Table 1

Selected attributes of *Dendrobaena alpina* from field sampling in *Fagetum carpathicum* near Ustrzyki Górne averaged across 2 sampling years - May to November

Characteristics	<i>Fagetum carpathicum</i>			
	<i>festucetosum</i> (site I)	<i>typicum</i> (site II)	<i>lunarietosum</i> (site III)	<i>allietosum</i> (site IV)
Mean biomass of clitellate Specimens (g)	0.99	1.01	0.72	0.78
Mean biomass of specimens with tubercula pubertatis (g)	0.67	0.82	0.54	0.71
Dominance (%)	56.0	36.0	24.8	11.4
Frequency (%)	43.1	61.1	37.5	20.4
Density (ind. · m ⁻²)	73.7 ± 52.0 ^a	163.2 ± 76.3 ^a	233.1 ± 125.1 ^a	47.4 ± 20.9 ^b
Mean biomass (g · m ⁻²)	24.30 ± 25.90	66.18 ± 30.23	89.56 ± 75.02	18.94 ± 8.95

Different letters in a row denote significant differences ($p < 0.05$)

Mature *D. alpina*, field-collected in 2008, had a mean mass of 1.4 g (n=6). These produced cocoons from the outset and averaged 1.83 cocoons worm⁻¹ month⁻¹ over 21 months at 15°C. Field-collected immature specimens, grown to maturity in the laboratory (at 0.95 to 1.4 g) produced no cocoons when maintained in isolation over a two month period. However,

when paired these recently matured adults (mean mass 1.32 g) produced 1.65 cocoons worm⁻¹ month⁻¹ (9 pairs over a period of 15 months). It is worth noting that all but two of the animals collected from the field proved to be *D. alpina*. The exceptions were two very small (at time of capture) *Lumbricus terrestris* L., but initial growth rate and lack of a “wriggling” escape response soon confirmed their identity.

D. alpina cocoons were yellow in colour and ovoid in shape (4 x 3 mm) with a mean mass of 19 mg (range 14 - 26 mg) (n=178). At 15°C, cocoons produced by recently matured adults during the first 2 months of production, hatched after a period calculated as 81 days with a hatching success rate of 82 %. Cocoons produced after this time, although showing embryo development through the translucent cocoon, mainly failed to hatch. On emergence, hatchlings had a mean mass of 18 mg, 100 % of cocoons produced a single wormling. Growth to maturity is shown in Figure 2. Maturity was normally reached after 7 to 8 months (at around 1.2 g) with the acquisition of a fully developed clitellum, although some individuals took 11 months to reach this stage. Tubercula pubertatis were developed after a period of 5 months.

Discussion

The Bieszczady Mountains in Poland are rich in earthworms species with 21 recorded from beech forest and meadows (DUMNICKA & KOSTECKA 2000). *D. alpina* abundance peaked here in July of one year followed by September the following. This compares with results for the same species from the Apuseni Mountains of Romania in the western Carpathians, where peaks in abundance and biomass were in August (POP & POP, 2004). In the Bieszczady region, *D. alpina* is an important earthworm species (dominance – min. 11.4 – max. 56.0 %; frequency – min. 20.8 – max. 61.1 % at different sites). As POP *et al.* (2007) have reported, *D. alpina* (and very similar earthworm species) has a dominant role in building up thick (10-12 cm) black organic part of soil horizons, being present in soils of different types: humico-silicatic, rendzina, acid black or podzolic brown soils, with raw or moder humus.

Data concerning the density of this earthworm in beech forests in the Bieszczady Mountains have shown similar values (mean 129.28 ± 68.58 ind. · m⁻²) to those recorded by POP *et al.* (2007) under fir trees (mean 126.99 ± 29.76 ind. · m⁻²), but the biomass in beech forests was much higher (means of 49.75 ± 35.02 g · m⁻² and 9.96 ± 2.27 g · m⁻²,

respectively). This could be connected with lower pH and fertility, which is usually connected with the soil under the fir tree.

Field examination in October and November in the Bieszczady Mountains showed that soil layers to 20 cm contained very few specimens, which may imply that this species winters beneath such depths. According to PLISKO (1971, 1973) and KASPRZAK (1986) *D. alpina* is usually situated in leaf litter and beneath the bark of decaying trees. Our findings imply that this species should be considered as more than epigeic in nature.

Laboratory findings have provided valuable information on the reproduction and growth rates of this species. Further experiments, might for example, provide improved growth rates by offering a range of culture materials with a greater organic content and more closely resembling the humic layers from which this species may be recovered in the field. Investigations as to why a large proportion of cocoons did not hatch might also be usefully looked into. This could well be an anthropogenic function of incubation conditions.

Considering the complex role of earthworms in ecosystem service provision and as “ecosystem engineers”, the studies conducted could be of significance. Collection of information relevant to the protection of earthworms in ecosystems is also important.
