1 **4. Abstract**

2 **Rationale, aims and objectives:** Emergency hospital readmissions within 30 days of discharge from

3 hospital are considered a marker for the quality of hospital care, patient experience, the discharge

4 process and integration with community services. This paper describes the frequency and variations in

5 cause of emergency readmissions at 30 and 90 days following discharge after acute stroke from two

6 stroke units.

7 **Methods:** Retrospective data collection of Hospital Episodes Statistics (HES) and Sentinel Stroke National

8 Audit Programme (SSNAP) of consecutive acute stroke hospital discharges over 24 months from 2017 to

9 2019 from two specialist stroke units in England. HES data were used to calculate the Charlson

10 comorbidity index (CCI). Covariates were analyzed for their association with readmission rate, including:

11 Age; Gender; CCI; Length of stay for first stroke admission; Living alone; Discharge to a care home;

12 Discharge receiving stroke specialist early supported discharge (ESD) rehabilitation; and stroke severity

13 as determined by NIHSS on stroke admission.

14 **Results:** From 2017 to 2019 there were 1999 live discharges with a primary diagnosis of stroke. Both

15 hospitals had a trend of increasing readmission rates with increasing stroke severity and comorbidity.

16 Longer length of stroke admission, especially for patients with increasing stroke severity, and receiving

17 ESD rehabilitation after discharge, reduced 90-day readmissions. This association was stronger at 90

18 days than at 30 days. Different readmission event rates were found at 30 and 90 days and when event

19 between the two hospitals.

20 **Conclusion:** Understanding differences in readmission event rates between hospitals at 30 and 90 days

21 can support planning local patient needs in the first weeks after stroke discharge and to investigate ways

22 for hospital to reduce the impact of readmission. It is recommended that stroke services use both 30 and

23 90-day readmissions to inform service evaluation and improvement.

6. Main text

29 **Introduction**

30 Unplanned, emergency hospital readmissions are undesirable for patients and add workload to hospital

31 services. The National Health Service (NHS) in England defines emergency readmissions as any

32 emergency readmission to hospital within 30 days of discharge [1]. Despite challenges to the validity of

33 emergency readmissions as a measure of quality of care, it continues to be used by NHS England as a

34 quality measure for in-hospital care, discharge planning, follow-up and community support [2-5].

35 Additionally, the World Health Organisation suggest availability of imaging, thrombolysis, length of

36 hospital stay and duration of rehabilitation contribute to variations in mortality and readmission[6].

37 Stroke is the leading cause of disability in the UK and accounts for more than 85,000 hospital admissions

38 per annum [7]. A recent NHS review of stroke services in England reported the national average 30-day

39 (all-cause) readmission rate after stroke as 11.3%[5]. NHS stroke services in England have been developed

40 aspiring to have an integrated, multidisciplinary pathway approach [7-9].   Readmission rates after stroke

41 are used as a measure of the effectiveness and integration of local stroke pathways from admission to

42 community rehabilitation[5]. Emergency readmissions are usually measured at 30 days of discharge from

43 a stroke event[1,5]. There is evidence to suggest that measuring emergency readmissions up to 90 days,

44 instead of the standard 30 days, may be more appropriate for older patients with decline in functional

45 mobility or activities of daily living[10]. The purpose of our study was to describe the rates and cause of

46 readmission at 30 and 90 days after discharge from two specialist stroke units in the southwest of

47 England. The secondary outcomes were to ascertain differences in the cause of readmission between

48 the two services, compare differences in readmission cause at 30 and 90 days after discharge and

49 consider the value of 90-day readmissions in informing stroke pathway quality improvements.

50 **Methods**

51 Data were collected from two district general hospitals, located six miles apart. Key characteristics of

52 both sites are detailed in table 1. The hospitals were of similar size and served an area with similar

53 diverse geography (urban and rural) with a demography featuring the greatest concentration of over 75-

54 year-olds in England. The hospitals both provided urgent and emergency care, medical care, surgery,

55 critical care, end-of-life care, outpatient, and diagnostic services. Each hospital had a combined stroke

56 unit – a specialist stroke unit with hyper-acute, acute and rehabilitation beds and early supported

57 discharge team. Both delivered thrombolysis and had access to interventional stroke treatments at

58   another site. Although the stroke units served a similar and overlapping population, there were

59   differences in the stroke service design and size. One site (site 2, table 1) had a lower number of annual

60   stroke admissions, a smaller number of beds and a higher proportion of patients discharged with stroke

61   specialist ESD rehabilitation which provided no cover out-of-hours and weekends.

62   **Table 1. Summary of hospital characteristics**

Characteristic	Site 1	Site 2
Population size	500,000	500,000
Hospital bed numbers	600	600
Stroke Unit admissions/year	800	480
Stroke Unit bed number	36	27
Consultant cover	5 days	5 days
Mean length of stay of stroke admission	14	18
Length of ESD provision	2 weeks	2 weeks
ESD cover	7 days, evenings	5 days, no evenings
% Discharged with ESD	37.8%	44.5%
Access to community rehabilitation beds	No	Yes

63   **Abbreviations:** ESD, Early Supported Discharge Community Rehabilitation Team

64

65   *Inclusion/exclusion criteria*

66   The initial stroke admission was defined as an emergency admission with primary discharge diagnosis of

67   ischaemic or haemorrhagic stroke (ICD-10 codes I61 to I64 inclusive); aged over 18 years old; admitted

68   between 1st September 2017 to 31st August 2019. Exclusions were patients with a diagnosis of

69   transient ischaemic attack, those who died during their acute stroke admission and those discharged

70   out-of-area. Inclusion as a readmission episode was defined as any emergency (unplanned) readmission

71   to either hospital site, with any diagnosis. No lower time limit on readmission (i.e. within hours of

72   discharge) was applied. The inclusion of two admitting hospitals, with overlap in population served,

73   captured patients discharged from one hospital and readmitted to the other.

74

75 *Ethical considerations*

76 This study protocol was reviewed and approved by the Clinical Audit Departments at Poole Hospital NHS

77 Foundation Trust and Bournemouth and Christchurch Hospitals NHS Foundation Trust. The study was

78 conducted in line with the hospitals' clinical governance and data protection policies.

79

80 *Data collection*

81 Data sources were Hospital Episodes Statistics (HES) and Sentinel Stroke National Audit Programme

82 (SSNAP). HES is an electronic record of every inpatient or day case episode of patient care in NHS

83 hospitals. SSNAP is a national prospective audit that collects a minimum dataset on patients with stroke

84 in England, Wales and Northern Ireland. SSNAP measures both the organisation and processes of care

85 provided to stroke patients against evidence-based standards[11]. HES and SSNAP data from 1st

86 September 2017 to 31st August 2019 were retrieved for all consecutive stroke admissions to any ward at

87 both hospitals. Data were retrieved for each patient every time they were re-admitted to either hospital

88 up to one year after discharge. HES data were cross validated with SSNAP data to ensure all stroke

89 admissions were captured. For each stroke admission case, information was obtained on primary

90 discharge diagnosis, admission National Institute for Health Stroke Scale (NIHSS), age, co-morbidities,

91 admission and discharge date, day of discharge, length of stay (LOS), discharging ward, discharge

92 destination, living alone at discharge and receipt of ESD community rehabilitation after stroke discharge.

93 HES data on subsequent emergency readmissions were retrieved for each case up to 90 days after

94 discharge from original stroke admission.

95

96 *Data sorting and cleaning*

97 Original stroke admissions coded with ICD-10 code I64x had their admission brain imaging reviewed and

98 re-coded as ischaemic or haemorrhagic stroke. Readmission codes were checked with case notes if

99 there was a possibility of a different underlying cause, for example, if a skin tear or fracture was caused

100 by a mechanical fall, or if a readmission diagnosis of paraesthesia was caused by seizures. Missing NIHSS

101 data were obtained from case notes where available. In total, there were 211 different readmission

102 diagnoses. Due to the large number of readmission diagnoses, two authors (CG and MD) jointly agreed

103 the grouping of similar clinical codes, for example all malignant cancers were grouped together, to aid

104 analysis and interpretation in line with the study objectives.

105

106   *Analysis*

107   HES data were used to calculate the Charlson Comorbidity Index (CCI) [12] which is an accepted method to

108   retrieve patient information on co-morbidities [13]. The Deyo algorithm was used to adapt ICD-10 data to

109   the CCI [14,15]. A higher CCI score indicates patients having greater co-morbidities.

110   Descriptive statistical analysis compared data from patients with 90-day readmission(s) against patients

111   with no readmissions; readmission rate over time from discharge; and 90-day readmission diagnoses

112   rates. The readmission rate was calculated based on the total number of patients readmitted at least

113   once within 90 days of discharge and if a patient was readmitted more than once, only the first

114   readmission episode was used in the analysis of readmission rate. For calculation of the most likely

115   diagnosis for readmission, all readmission episodes were included.

116   Logistic regression analysis was performed to determine the predictors of readmission. The variables

117   were identified prospectively from published literature on causes for stroke readmissions [16]. The

118   variables were: age; gender; CCI; length of stay for first stroke admission; living alone; discharge to a care

119   home; discharge with ESD rehabilitation; and stroke severity as determined by NIHSS on stroke

120   admission. Variables were excluded when there was insufficient evidence to refute the null hypothesis

121   (coefficient corresponding to variable = 0), that is the factor had no effect on readmission rate. The final

122   model only included variables with p-value < 0.05. The outcomes for the model were readmissions

123   within 90 days. The association between readmission rate and readmission diagnoses were analysed

124   using the Chi Squared Test. HES data on discharge destination was only available for 35% records,

125   therefore, analysis of discharge destination and living alone status was not analysed.

126

127   **Results**

128   The study included 1999 live discharges with a primary diagnosis of stroke. 72 (3.6%) patients died

129   within 90 days of discharge. 497 patients (26% of patients alive at 90 days) were readmitted at least

130   once as an emergency within 90 days to either hospital, 53.3% were female. 16.2% (313) were

131   readmitted within 30 days, and 25.8% (497) within 90 days. The median time for readmission occurring

132   within 90 days of discharge was 19 days (IQR=6-46 days). The majority (n=361, 73%), had one

133   readmission in 90 days, and one patient was re-admitted eight times in 90 days. Table 2 shows the

134   relationship between the variables of age, comorbidity, stroke severity, length of stay and readmission at

135   90 days. Age did not have a statistically significant relationship with 90-day readmission. Both shorter

136   LOS and NIHSS appear to be associated with increased 90-day readmissions and when both sites' data is

137   combined, this relationship becomes significant (Table 2). CCI had a significant association with 90-day

138   readmission at each site. These associations were further analyzed and will be discussed next.

Co-morbidity (Charlson Comorbidity Index) and Readmission Rate

The relationship between CCI and readmission rate was analyzed as a logistic regression model and testing the significance of factors using the Log-Likelihood Ratio Test. The analyses determined that CCI does have a significant effect on the readmission rate, (p-value < 0.001) with co-morbidity being more significant for re-admission at site 1 (OR 1.173, 95% CI 1.132, 1.218) than site 2 (OR 1.129, 95% CI 1.090, 1.172).

148   CCI scores were grouped into mild (CCI <2), moderate (CCI 3-5) and severe (CCI >5) comorbidity and

149   summarised in Table 3. According to Figure 1, there were differences in CCI severity and readmission

150   rates across the two sites. Table 3 shows grouping of comorbidities into mild, moderate and severe that

151   demonstrates site differences in readmissions according to CCI severity group. Site 1 had a higher

152   number of 90-day readmissions in patients with mild comorbidities, whereas site 2 had a higher number

153   of 90-day readmissions in patients with severe comorbidities.

154   **Table 3. Proportion of 90 day readmission cases with mild, moderate and severe comorbidity**

CCI Grouping	Site 1 % Readmission cases	Site 2 % Readmission cases	Total
Mild	42.41%	25.48%	35.96%
Moderate	32.44%	32.15%	32.33%
Severe	25.15%	42.37%	31.71%

155   **Abbreviations:** CCI, Charlson comorbidity index

156

157   *Length of stroke admission, stroke severity and readmission rate*

158   Table 4 shows the analysis of different models on readmissions for each site. Firstly, stroke admission

159   LOS was compared against null model and was shown to be significant for site 1 (p <0.001, as compared

160   against intercept model) and non-significant for site 2. When stroke severity (NIHSS) was included with

161   LOS, this model is significant fit (p<0.05) for 90-day readmission rates than LOS alone. The addition of

162   the variables successively to the model improves the fit significantly for site 1, but remained non-

163   significant for site 2, with the inclusion of the interaction not improving model fit when compared to

164   Model 2 (Table 4).

165   **Table 4. Comparison of combined model with 90-day re-admission rate**

Model	(1) vs null model LoS	(2) vs (1) Los + NIHSS	(3) vs (2) Interaction model	P* 	P
	(1)	(2)	(3)	(1 vs 3)	(2 vs 3)
Site 1

Site 2					
30-day readmission rate	0.6395	0.4704	0.1396	0.2588	0.1396
90-day readmission rate	0.06265.	0.1439	0.7984	0.3327	0.7984

Signif. codes: 0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1

166

167   Model visualization (shown in figure 1) shows the interaction of LOS and NIHSS score had a significant

168   effect on readmission rate for patients discharged from site 1 and is more significant for readmission

169   within 30 days. For example, patients admitted to site 1 with a NIHSS score of 20 and >7 days LOS

170   experienced a lower 30- and 90-day readmission rate (16%,46%) than those who had <7 days LOS

171   (28%,57%). For site 2, there was insufficient evidence to suggest LOS and NIHSS had an effect on re-

172   admission rate (P-value for interaction p > 0.1).

173
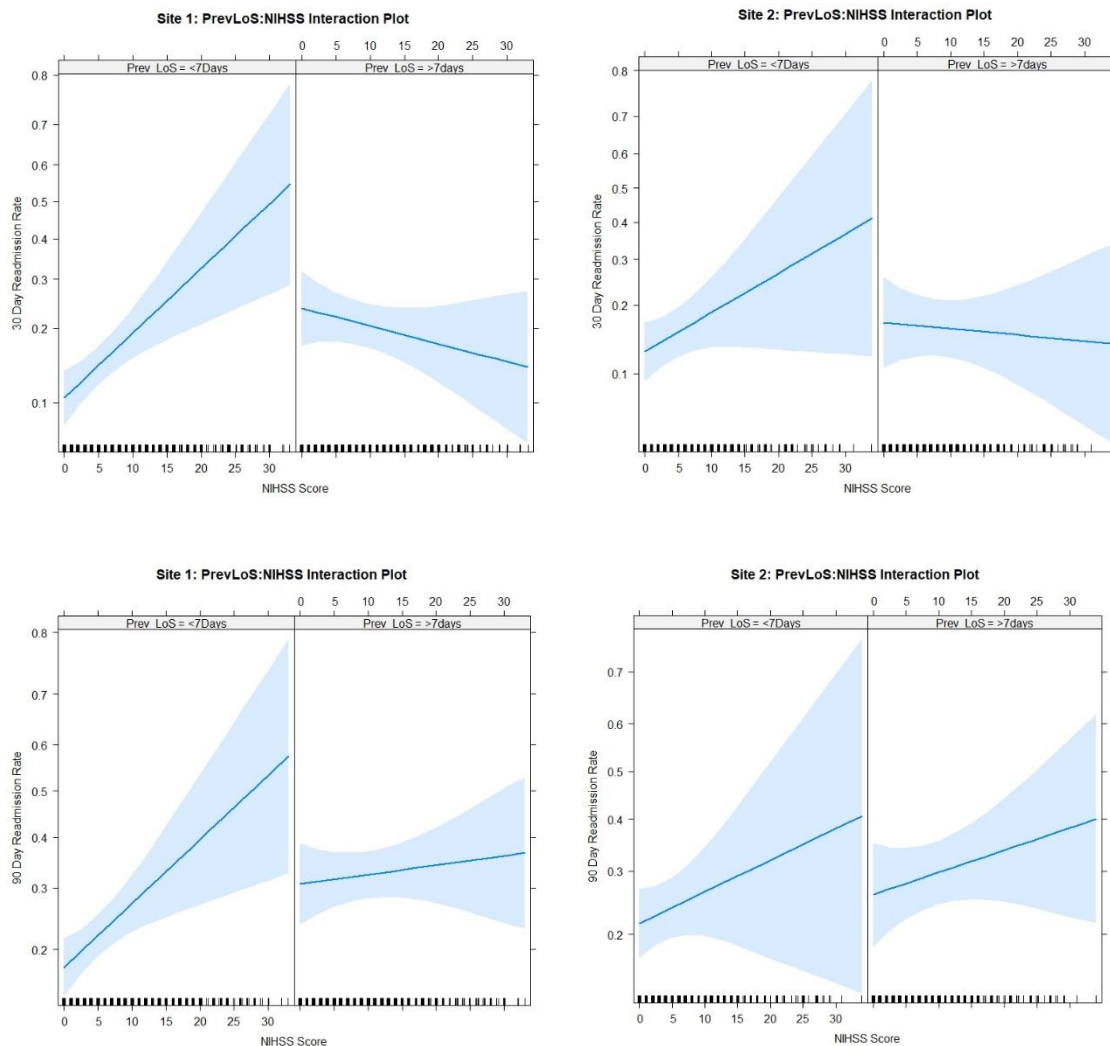

174   **Figure 1: Interaction plots showing stroke admission LOS, NIHSS and 30/90 day re-admission rate**
175   **for sites 1 & 2**

176

177 *Community stroke specialist rehabilitation (Early Supported Discharge) and readmission rate*

178 SSNAP data were used to ascertain if the patient was discharged after their stroke to receive community

179 rehabilitation from the stroke Early Supported Discharge (ESD) service. For 30-day readmissions, there

180 was no significant association between receipt of ESD rehabilitation and readmission (Table 5). However,

181 this changed for 90-day readmissions, with ESD rehabilitation associated with significantly lower

182 readmissions in site 1 (p=0.004), with this association strengthening with data from both sites were

183 combined (p=0.001).

184 **Table 5. Readmissions by receipt of Early Supported Discharge rehabilitation after stroke**

185 **discharge**

Access to ESD after stroke discharge	Site 1		Site 2		Both sites

187 *Cause of readmission*

188 Table 6 shows the top five diagnoses for 90-day readmission according to CCI categories of mild (CCI ≤2),

189 moderate (CCI 3-5)and severe (CCI >5). The most frequent diagnoses were: infection, ischaemic stroke,

190 falls and musculoskeletal problems (Table 6). Comparisons in cause of readmission were made between

191 to the two hospitals due to the similar, and overlapping, population and non-stroke specific community

192 services (Table 1) . Similar causes for readmission were observed at both hospitals, but in different

193 proportions.   For example, site 2 saw a greater proportion of ischaemic stroke (site 1=8.98%, site

194 2=14.23%) and site 1 saw more infections (site 1=19.4%, site 2=14.23%). Both saw a similar proportion

195 of falls (site 1 = 8.51%, site 2=8.46%) and musculoskeletal problems (site 1=5.91%, site 2=5.77%). At site

196 2, patients with less severe comorbidity, over a quarter were readmitted with an ischaemic stroke, whilst

197 at site 1 readmission with ischaemic stroke was not a 'Top 5' diagnosis. For site 1, infection was the

198 most likely cause for readmission, including those with less severe comorbidity. Further analysis of case

199 notes would help to determine the reasons for these trends.

200

201 **Table 6. Top five 90-day readmission diagnoses according to site and co-morbidity severity**

Site 1

(n)	Comorbidity severity	1st	2nd	3rd	4th	5th

202

203 **Discussion**

204 The purpose of our study was to describe and compare 30 and 90-day causes of readmission after

205 discharge from two specialist stroke units in the southwest of England. The two sites are within

206 proximity and over-lapped the population served, therefore, this study provides a comprehensive data

207   set of readmissions after stroke in the local population, also capturing patients who were admitted with

208   a stroke to one site and readmitted to the other site.

209

210   Patient-based factors, such as age, sex and comorbidity drive underlying demand for emergency

211   admission in the over 65s[3]. With the addition of stroke severity, these patient-based factors are similar

212   in stroke patients [17]. Our results reflect high readmission rates and causes reported in the literature[4,16,18].

213   In our study, there was a trend towards increased readmission with age, but this was not a significant

214   relationship[4]. Comorbidity (CCI) and stroke severity (NIHSS) were associated with increased 90-day

215   readmission, also consistent with previous research[3,17]. However, when individual sites were compared,

216   site 1 had increased 90-day readmissions for less severe strokes and fewer comorbidities. A longer LOS

217   of more than 7 days for increasing stroke severity (NIHSS) tended to reduce readmissions. This

218   association was stronger in site 1. These results suggest that stroke services need to monitor the impact

219   of reducing average days of inpatient care and consider risk of readmission as part of their discharge

220   planning and ongoing support. This is particularly relevant with inpatient stroke services reducing length

221   of stay and increasing rehabilitation in the community.

222

223   Our results suggest that support after leaving hospital, in this study this was in the form of ESD

224   rehabilitation, may be an important factor for 90-day readmissions. Additional support from ESD

225   services on leaving hospital may reduce readmissions for common post-stroke complications such as

226   aspiration pneumonia, urinary tract infections and falls, or support secondary prevention interventions.

227   This association needs further research. The importance of relationships between community and

228   hospital services and how they provide continuity of care affects emergency bed use in UK hospitals[3].

229   Not all community services may benefit patients recovering from stroke and these need careful review. A

230   meta-analysis of ESD studies in stroke patients showed no significant differences in readmissions

231   between control and ESD rehabilitation[19]. Our study found no association of ESD rehabilitation services

232   on readmission at 30-days, whereas there was a significant reduction in 90-day readmissions suggesting

233   there may be a key period after discharge where ESD rehabilitation can impact readmissions at around

234   three months post discharge. ESD rehabilitation may impact readmissions by reducing complications

235   associated with stroke and supporting stroke secondary prevention management. Further research is

236   required to explore this association and other models of community support for patients not eligible for

237   ESD service.

238

239   Comparing cause of re-admission across the two sites with similar patient populations provided a unique

240   opportunity to review differences in the stroke pathway to inform future service improvements. Overall,

241   our study's re-admission causes were similar to findings in Abreu et al's[4] larger study, with the most

242   common being stroke recurrence and infection. Falls and musculoskeletal problems featured in

243   readmissions for all stroke severities and are potentially avoidable readmissions with further community

244   and rehabilitation interventions. However, the rates of readmission cause were different in the two

245   sites. For example, site 2 had more readmissions due to falls and no ESD service at weekends and

246   evenings. Although further research is needed explore these trends, highlighting and exploring how

247   differences in service provision may impact on readmission with falls can lead to quality improvements

248   through sharing of good practice.

249

Limitations

251 This study has several limitations that require our results to be interpreted with caution. Firstly, the

252 study was limited due to retrospective data collection and the data quality was reliant on the HES and

253 SSNAP databases and clinical documentation in medical records. Using a combination of HES and SSNAP

254 data, along with cross-referencing data sets where appropriate, led to increase in accuracy for stroke

255 specific ICD-10 codes, however, the causes of readmission may not be accurate due to administrative

256 coding errors of readmission diagnoses. Including data sets from both hospitals enabled capture of

257 patients that were readmitted to either hospital, increasing the accuracy of readmission activity in the

258 local population, but could potentially make comparisons between hospital sites inaccurate. Secondly,

259 there was missing data regarding discharge destination and whether the patient was living alone, so we

260 were unable to analyze whether this impacted readmissions. Deprivation and geographical access are

261 known drivers for emergency bed use in the UK [3]. Due to the retrospective data collection, we were

262 unable to collect accurate geographical data from the HES database to analyze socio-economic and

263 geographic relationship to readmission after stroke. Thirdly, variability in readmission rate is not only

264 influenced by fluctuations in covariates but also by differences in its calculation. The dominator can be

265 inflated by inclusion of patients who died during admission, or within the timescale being measured (in

266 this study, 30 and 90 days). We were unable to collect data on those discharged after hospitalisation for

267 acute stroke who died within the 30- or 90-day period and, therefore, their inclusion in the denominator

268 will result in readmission rates being underestimated. Finally, measuring stroke severity at admission did

269 not account for improvement with thrombolysis or thrombectomy.

270 **Conclusion**

271 This study confirms other research that stroke recurrence and infection are the top causes for

272 readmission after stroke. Information on rates and cause of readmission may help stroke services in

273 targeting transition and post-discharge interventions. It is important to understand variations across

274 services and preventable factors that may influence readmission. When measuring 90-day readmissions,

275 a time point not routinely collected by NHS stroke services, this study highlights shorter length of stroke

276 hospital stay and lack of access to ESD service is associated with increased 90-day readmission. Further

277 prospective research is required into the associations between shortening length of stroke hospital stay

278 and ESD services on cause and rate of readmissions.
