Abstract: Immune checkpoint blockade targeting *PDCD1* (PD-1) or *CD274* (PD-L1) has demonstrated efficacy and interest across multiple cancers. However, the exact determinants of the response and cancer-specific molecular features remain unclear. A recent pan-cancer study identified a *PDCD1/CD274*-related immunotherapy network of 40 genes that had differential patient survival associations across multiple cancers. However, the survival relevance of this network in mesothelioma could not be assessed due to a lack of available survival data for the mesothelioma study included. Mesothelioma, a rare cancer that most commonly arises in the pleural membranes around the lung, does have immune checkpoint blockade as an approved treatment strategy, yet questions over its efficacy remain. RNA-seq data from 87 pleural mesothelioma patients were interrogated on cBioPortal to assess the role of the *PDCD1/CD274* network identified in a previous study, in addition to identifying repurposed drugs that may have therapeutic efficacy. Extensive literature searches were conducted to identify known information from the literature around the genes shown to impact patient survival (*CCR5*, *GATD3A/GATD3*, *CXCR6*, *GZMA*, and *TBC1D10C*). The same literature validation was performed for putative repurposed drugs that were identified as potential immunotherapeutic adjuvants in the context of mesothelioma (disulfiram, terfenadine, maraviroc, clioquinol, chloroxine, and oxyphenbutazone). Only disulfiram returned a specifically focused research article based on the literature search. This article demonstrated cytotoxicity in a panel of five human MPM cell lines of mixed histology (epithelioid, biphasic, and sarcomatoid). There was little information on the remaining five drugs, yet the clear preclinical efficacy of disulfiram validates the methodology used herein and prompts further exploration of the remaining drugs in mesothelioma. This study ultimately sheds light on novel preclinical information of genes related to *PDCD1/CD274* in mesothelioma, as well as identifying putative drugs that may have therapeutic efficacy either independently or as an immunotherapeutic adjuvant.

1. Introduction

Mesothelioma is a rare form of cancer that arises from the mesothelial cells that line organs such as the heart (pericardial mesothelioma), abdomen (peritoneal mesothelioma), testes (testicular mesothelioma), and the lungs (pleural mesothelioma) [1]. Pleural mesothelioma is the most common of these, accounting for approximately 90% of mesothelioma cases [2]. Outcomes remain poor, with a median overall survival of 8 months based on pleural and peritoneal mesothelioma data from the National Cancer Institute's Surveillance, Epidemiology, and End Results–Medicare database [3]. The standard first-line therapy for mesothelioma was traditionally platinum-based therapy and anti-folates, though, as with many cancers, there have been significant efforts to utilize immunotherapy, particularly immune checkpoint blockade [4].

Immune checkpoint blockade relies on the premise that blocking the immune-down-regulatory signals that cancer cells exhibit to evade the immune system leads to the immune system remaining active and targeting the cancer [5,6]. The most common targets for immune checkpoint blockade are CTLA-4, PD-1 (*PDCD1*), and PD-L1 (*CD274*) [7]. However, the response to immune checkpoint blockade in mesothelioma has been mixed at best and is often associated with side effects [8]. Although first-line combination nivolumab (anti-PD-1) and ipilimumab (anti-CTLA-4) was approved in October 2020 for unresectable MPM [9], based on the CheckMate 743 trial [10], side-effects and adverse-related events persist. The efficacy of the therapy has also been questioned, with a comparative study finding no survival benefit in the CheckMate 743 trial relative to a trial studying cisplatin + pemetrexed + bevacizumab against cisplatin + pemetrexed [11]. As such, there is a need to delineate the molecular differences underpinning immune checkpoint blockade on a per-cancer type basis and, in the case of mesothelioma, develop further understanding of its biology, pathology, and drivers of response to therapy.

A recent study [12] utilized patient RNA-seq data from cBioPortal [13,14] to interrogate the association between expression of genes in a *PDCD1/CD274* network and patient survival on a pan-cancer basis. The study, beginning with *CD274* and *PDCD1*, identified 40 genes that were correlated with *PDCD1* or *CD274* (either positively or negatively) and undertook Kaplan–Meier analysis based on patient RNA-seq data to identify genes that were significantly associated with patient outcomes [12]. Different patterns of clinical relevance emerged in terms of which genes of the network were significant and how they influenced survival, with renal and esophageal cancers being notably different from the thirteen other cancer types. A limitation of the study, however, was that the mesothelioma study included (Mesothelioma (TCGA, Firehose Legacy)) lacked usable survival data and, therefore, the clinical relevance of the genes in this *PDCD1/CD274* network could not be assessed [12].

However, a second study (Mesothelioma (TCGA, PanCancer Atlas) [15]) on the same patient cohort is available on cBioPortal, which contains the survival data alongside the “mRNA expression z-scores relative to diploid samples (RNA Seq V2 RSEM)” data format analyzed in the original study [12]. Due to the inclusion criteria in the preceding study, the Mesothelioma (TCGA, PanCancer Atlas) study could not be included. Therefore, this present study assessed the clinical relevance of *PDCD1*, *CD274*, and the 40 pan-cancer correlated genes in the *PDCD1/CD274* network for malignant pleural mesothelioma (MPM). Five genes (*CCR5*, *GATD3A/GATD3*, *CXCR6*, *TBC1D10C*, and *GZMA*) were shown to be significantly associated with survival in mesothelioma patients, with each demonstrating high expression to be significantly associated with patient survival and in silico drug repurposing identifying potentially repurposed prospective immunotherapeutic adjuvants for mesothelioma.

2. Materials and Methods

2.1. Study Selection

In order to assess the clinical relevance of *CD274*, *PDCD1*, and genes in the *PDCD1/CD274* network, the cBioPortal database (<https://www.cbioportal.org/>, accessed on 12 January 2022) was used [13,14]. The database contains easily accessible patient-level multi-omics data for over 300 individual studies/analyses. The “Mesothelioma (TCGA, PanCancer Atlas)” study was the dataset of choice, as it contains the same patients from the “Mesothelioma (TCGA, Firehose Legacy)” study used in the preceding publication [12].

2.2. Identification of Genes of Interest

A total of 42 genes (*CD274*, *PDCD1*, and the 40 genes in the *PDCD1/CD274* network) were obtained from the preceding publication [12], as these were highlighted in the first study as being correlated pan-cancer either positively or negatively with either *CD274* or *PDCD1*.

To validate the interconnectivity between these genes/proteins, which was not performed in the original study, STRING [16] was used. The “Multiple proteins” search function was used; at which point, the 42 network constituents were inputted, and “*Homo sapiens*” used as the species. After ensuring each input was mapped to the appropriate STRING entry, the resultant protein connectivity map was saved and exported, alongside the node connectivity assessment.

2.3. Assessing the Mesothelioma-Specific Importance and Survival Association of PDCD1, CD274, and the 40 PDCD1/CD274-Related Genes

To assess the survival relevance of the PDCD1/CD274 network, the “Mesothelioma (TCGA, PanCancer Atlas)” study on the cBioPortal homepage was selected and “Explore Selected Studies” was chosen. Patients with “mRNA expression z-scores relative to diploid samples (RNA Seq V2 RSEM)” were selected from the “Genomic Profile Sample Counts” section and each gene was queried, in turn, using the “Gene Specific” tab under “Charts”. Patients were divided into high and low expression of each gene, in turn, based on the median value. “mRNA expression z-scores relative to diploid samples (RNA Seq V2 RSEM)” was the “type” of mRNA expression analysis performed. A Kaplan–Meier plot was then computed based on the two groups (low and high expression of each gene in turn) to determine the putative association of each gene with patient survival. A raw $p \leq 0.05$ (based on a survival logrank test as calculated by cBioPortal) was considered statistically significant for that gene, and the determination of low or high expression being beneficial for the patient was determined by examination of the overall pattern of the curve. Due to the exploratory nature of this and the preceding study, multiple comparison corrections on p -values were not strictly required [17,18] and the interpretation downstream in this article considers raw p -values. However, Benjamini–Hochberg corrections were performed for reference on the p -values for the Kaplan–Meier curves <https://www.sdmproject.com/utilities/?show=FDR>, accessed on 28 October 2022) and are available in Supplementary Table S1, as is the raw p value distribution (Supplementary Figure S1).

For genes that were statistically significantly associated with survival, the gene expression and patient survival data were downloaded from cBioPortal and input to KMplot using the upload function [19,20]. This allowed for the recapitulation of the cBioPortal groupings and analysis and enhanced it by also calculating hazard ratios.

To validate the importance of these genes in the context of mesothelioma, cBioPortal was again accessed and the “Mesothelioma (TCGA, PanCancer Atlas)” study on the cBioPortal homepage was selected and “Query by Gene” was chosen. “mRNA expression z-scores relative to diploid samples (RNA Seq V2 RSEM)” was selected as the “type” of mRNA expression and the default Patient/Case set was used. PDCD1 and CD274 were then input separately in turn, and the Co-Expression tab under the “mRNA Expression, RSEM (Batch normalized from Illumina HiSeq_RNASeqV2) (82 Samples)” setting was used to identify correlations between PDCD1/CD274 and the significant genes (by Kaplan–Meier analysis) identified above.

2.4. Putative Drug Identification & Literature Searches for Gene & Drug Validation

A list of drugs relevant to the present study were obtained from the preceding study [12]. The drugs that were selected were those that targeted genes that were identified to have a statistically significant survival association in mesothelioma based on the results from the above methods section.

To assess the depth of the literature available for the drugs and their relationship to mesothelioma, the following search term was used on PubMed: “(mesothelioma[Title/Abstract]) AND ([DRUG])”, where “[DRUG]” was replaced with each drug in turn. The date of the search was 24 June 2022. The resultant literature was scanned at the abstract level in the first instance, and then full papers were accessed if the paper was deemed relevant (based on the simple criteria of assessing to what extent the drug has been tested

in mesothelioma). A second search was performed to identify non-published links such as current clinical trials.

The depth of the literature available for any genes linked to patient survival in mesothelioma was also assessed. The following search term was used on PubMed: “(mesothelioma [Title/ Abstract]) AND ([OFFICIAL GENE SYMBOL])”, where “[OFFICIAL GENE SYMBOL]” was replaced with each official gene symbol in turn. The date of the search was 24 June 2022. The resultant literature was scanned at the abstract level in the first instance, and then the full papers were accessed if the paper was deemed relevant.

3. Results

3.1. Validation of the Connectivity of the PDCD1/CD274 Network

To validate the network identified in the previous study and extend the analysis, STRING v11.5 was accessed in order to determine the connectivity between the 42 network constituents, as shown below in Figure 1:

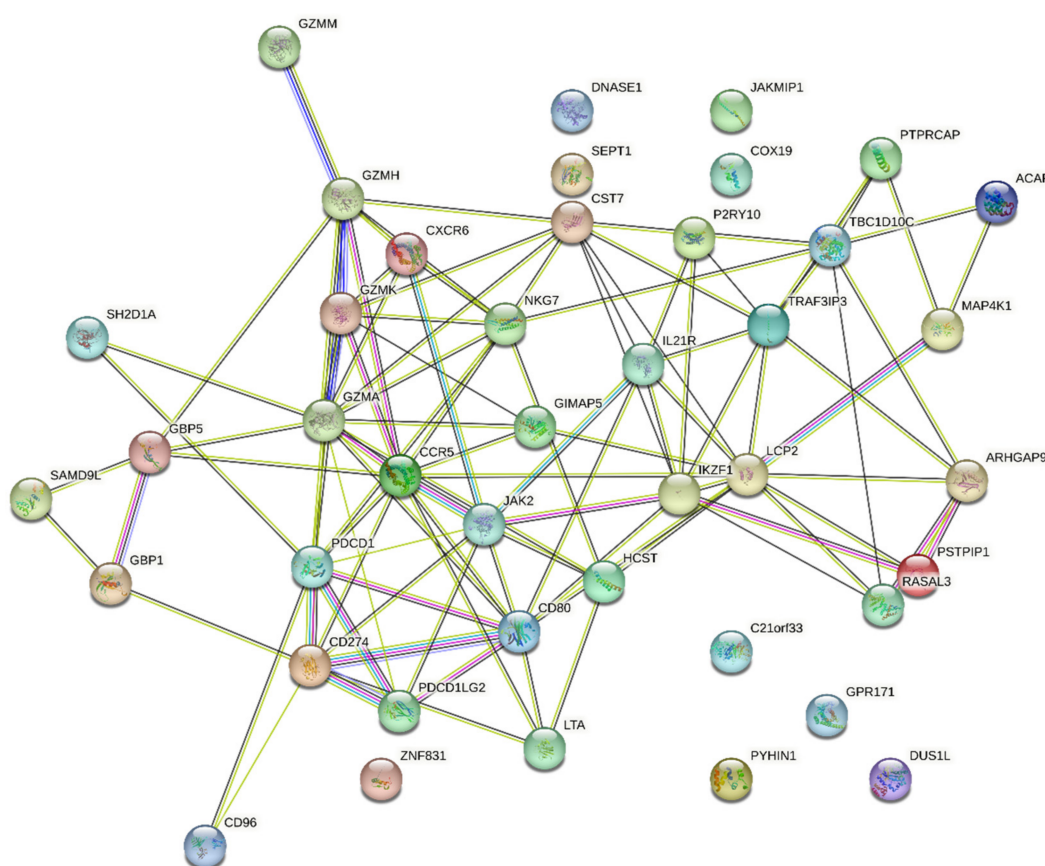

Figure 1. STRING connectivity map of the PDCD1/CD274 network identified in the preceding study. As identified by STRING, the protein–protein interaction (PPI) enrichment p -value was less than 1.0×10^{-16} .

As demonstrated above in Figure 1, there is a significant degree of interconnectivity between the 42 network elements in the PDCD1/CD274 network from the previous study [12], which is further supported by the node connectivity assessment (Supplementary Table S2). As this STRING analysis is conducted independently of the cBioPortal platform, it provides a confirmation of the validity of the PDCD1/CD274 network, warranting further investigation.

3.2. Identifying the Clinical Relevance of *PDCD1*, *CD274*, and 40 *PDCD1*/*CD274*-Related Genes

To identify the clinical relevance of *PDCD1*, *CD274*, and the 40 genes in the *PDCD1*/*CD274* network [12], the cBioPortal was accessed, as described in Materials and Methods [13,14]. Of the 42 genes, only five had a statistically significant p -value ($p < 0.05$) in pleural mesothelioma based on the logrank test calculated by cBioPortal (Supplemental Figure S1). To calculate hazard ratios, the cBioPortal analysis was recapitulated in KMplot [19,20]. The survival curves for the five genes are shown below in Figure 2.

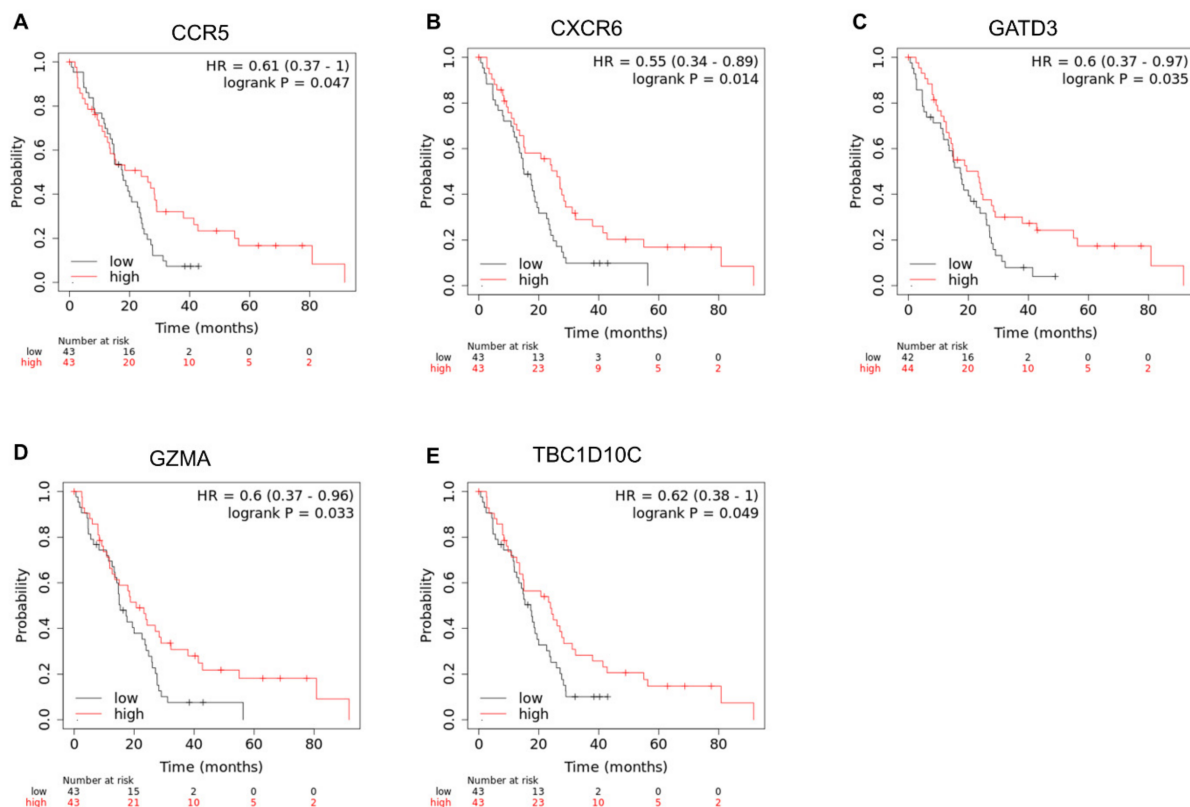

Figure 2. Statistically significant Kaplan–Meier plots for *CD274*, *PDCD1*, and 40 *PDCD1*/*CD274*-related genes. Only statistically significant survival curves are shown. For each graph above (A–E), the overall survival in months can be seen on the x -axis, whereas the probability of survival is shown on the y -axis. Hazard ratio (HR) and logrank p value for the analysis is indicated. High expression of *CCR5* (A), *CXCR6* (B), *GATD3A*/*GATD3* (C), *GZMA* (D), and *TBC1D10C* (E) is shown in red, whereas low expression for each gene is shown in black. Data were generated using the mRNA expression z-scores relative to diploid samples (RNA Seq V2 RSEM) for the Mesothelioma (TCGA, PanCancer Atlas) study [15] available on cBioPortal, and Kaplan–Meier analysis was performed via Kaplan–Meier Plotter.

The mesothelioma-specific correlations between these genes and *PDCD1*/*CD274* can be seen in the co-expression analysis results in Supplementary Figures S2–S6, which shows that all the genes here are, in a mesothelioma context, significantly correlated either positively or negatively.

In terms of the genes correlated with *CD274* (*CCR5* and *GATD3A*/*GATD3*), the previous study [12] found that a high expression of *CCR5* (a gene positively correlated with *CD274*) was beneficial for patients with liver, head and neck, and melanoma cancers, which was also the case for mesothelioma (Figure 2A). However, the survival profile for mesothelioma shown above is unique, as a high expression of *GATD3A*/*GATD3* (a gene negatively correlated with *CD274*) was shown to be beneficial for patients (Figure 2C), something which was only identified in pancreatic cancer in the previous study [12].

In terms of the genes correlated with *PDCD1* (*CXCR6*, *GZMA*, *TBC1D10C*, all positively correlated), a high expression of all of these were shown to be beneficial for patients in mesothelioma (Figure 2B,D,E). This is consistent with multiple cancers in each case. A high expression of *CXCR6* was shown to be beneficial for patients in cervical, liver, head and neck, breast, melanoma, lung, and bladder cancers [12]. A high expression of *GZMA* was shown to be beneficial in breast, melanoma, and bladder cancers [12]. Finally, a high expression of *TBC1D10C* was shown to be beneficial in cervical, liver, head and neck, breast, melanoma, and lung cancers [12].

3.3. Drug Repositioning

The preceding study [12] was accessed to retrieve drugs targeting the genes identified above (initial analysis was via the DRUGSURV database [21,22]). Six drugs (disulfiram, terfenadine, maraviroc, clioquinol, chloroxine, and oxyphenbutazone) targeting five genes (*CCR5*, *CXCR6*, *TBC1D10C*, *GZMA*, *GATD3A/GATD3*) were relevant. A literature search was then conducted on PubMed to investigate the degree to which each gene and drug had been investigated in mesothelioma, summarized in Table 1.

Table 1. Assessment of the literature linking mesothelioma and the genes identified in Figure 2 and literature validation of the putative repurposed drugs identified. Approval information was taken from [12] Bolded entries indicate search terms used.

Search Terms		Official Full Name (NCBI Gene)	Relevant Literature	
Mesothelioma [Title/Abstract] AND	CCR5	C-C motif chemokine receptor 5	(Davidson et al., 2007) [23]	
	CXCR6	C-X-C motif chemokine receptor 6	None	
	TBC1D10C	TBC1 domain family member 10C	None	
	GZMA	Granzyme A	(Bacolod et al., 2019) [24] (Nishimura et al., 2009) [25]	
	GATD3A/GATD3	Glutamine amidotransferase-like class 1 domain-containing protein 3/A	None	
Search Terms		Putative Target(s)	Approval Status	Relevant Literature
Mesothelioma [Title/Abstract] AND	Disulfiram	CCR5, CXCR6	FDA approved (alcoholism)	(Cheriyian et al., 2014) [26]
	Terfenadine	CCR5	Withdrawn	None
	Maraviroc	CCR5	FDA Approved (HIV)	None
	Clioquinol	CXCR6	FDA Approved (Tinea infection)	None
	Chloroxine	CXCR6	FDA Approved (Seborrheic dermatitis, Pityriasis simplex)	None
	Oxyphenbutazone	CXCR6	Withdrawn	None

Of the five genes identified to influence patient survival, only two were shown to be linked to mesothelioma in the literature. These were *CCR5* [23] and *GZMA* [24,25]. However, the literature linking *CCR5* was limited [23]. Davidson et al. (2007) analyzed chemokine receptor expression in malignant mesothelioma (11 samples), reactive mesothelium (16 samples), and lymphocytes in effusions, and found that chemokine receptors were infrequently expressed in malignant mesothelioma, whereas it was uniformly negative in reactive mesothelium [23].

Literature validation also highlighted the potential cytotoxic effect of disulfiram in mesothelioma [26], discussed in more depth below.

4. Discussion

This study builds on previous work which identified a 42-gene *PDCD1/CD274* network [12]. The original study used only cBioPortal analysis, though on a pan-cancer basis, to identify this network. To validate the network through an independent platform, STRING [16] was used to assess the degree of interconnectivity between the network constituents. As shown in Figure 1, there is a significant degree of interconnectivity, and this is supported by the PPI enrichment *p*-value of $<1.0 \times 10^{-16}$. Per STRING, this highlights that the input list—the *PDCD1/CD274* network—has significantly more interactions between the network elements than would be expected for a random list of proteins. Thus, this PPI enrichment indicates that the proteins are, at least partially, biologically connected [16].

In Figure 1, there is evidence that certain “hubs” are identifiable. For example, *CCR5*, which was identified in this study as high expression being significantly associated with mesothelioma patient survival, is one of the most interconnected nodes, with a node degree of twelve (Supplementary Table S2). Similarly, *GZMA*, identified again in this study as beneficial for patient survival, was also significantly connected to other genes/proteins in the network, with a node degree of fourteen. This independent STRING analysis confirms the potential importance and composition of the *PDCD1/CD274* network.

As demonstrated in Figure 2, five genes (*CCR5*, *CXCR6*, *GZMA*, *TBC1D10C*, and *GATD3A/GATD3*) from the *PDCD1/CD274* network demonstrated that high expression levels were associated with improved outcomes in pleural mesothelioma. Furthermore, the co-expression analysis (Supplementary Figures S2–S6) supports the importance of these five genes in relation to *PDCD1/CD274* specifically in the context of mesothelioma, as all five were statistically significantly correlated with either *PDCD1*, *CD274*, or both. Apart from *GATD3A/GATD3* (encoding glutamine amidotransferase class 1 domain containing 3 protein), of which little is known for its role in cancer, the other genes are all involved in the immune response.

Two of these genes (*CCR5* and *CXCR6*) encode for proteins that act as chemokine receptors, primarily involved in the recruitment and migration of immune cells, and they can play complex roles in cancer. The role of *CCR5* and other chemokine receptors in cancer is multifactorial and has previously been reviewed in depth [27]. Both pro- and anti-tumor activities have been identified. The recruitment of immune cells into the tumor microenvironment is believed to underlie many of the impacts of chemokines. A range of different immune cells can be found within the tumor in pleural mesothelioma, with significant patient heterogeneity [28] and a bias towards immunosuppressive cells. The number and nature of immune cells present in pleural mesothelioma is believed to have prognostic value [29] and may impact the response to immunotherapy. Tumor-associated macrophages (TAMs) comprise a large proportion of the immune milieu and are associated with poor outcomes. These cells are likely derived from peripheral blood monocytes recruited via mesothelioma cell-derived chemokines. While the CCL5-*CCR5* axis is capable of such recruitment, evidence suggests that *CCR2* (via interactions with CCL2), rather than *CCR5*, is the dominant driver in MPM [30].

CXCR6 and its ligand CXCL16 are responsible for the recruitment of lymphocytes, including both CD4⁺ (specifically Th1) and CD8⁺ T cells, into areas of inflammation [31]. Hypermethylation of this gene has been identified as a potential biomarker for the identification of mesothelioma in those exposed to asbestos [32]. Although a high expression of *CXCR6* and its ligand have been proposed to have a role in cancer progression and metastasis in several cancers, including prostate and breast cancer [33], that is not consistent with the protective role seen in the mesothelioma data from this study.

In addition to the expression on immune cells, *CCR5* can also be expressed by a range of cancer cells, including hematological (acute lymphoblastic leukemia [34], Hodgkin's lymphoma [35], and multiple myeloma [36]) and solid tumors (liver [37], head and neck [38], melanoma [39], and breast [40]). Along with other chemokine receptors and leukocyte markers, *CCR5* can be occasionally detected on a minority of malignant mesothelioma cells [23], with 1/11 samples showing *CCR5* staining. Although there may be a role

for tumor-intrinsic chemokine receptor expression, the correlation of high *CCR5* (and potentially *CXCR6*) and improved outcomes in this study is likely to reflect chemokine receptor expression levels on T cell subsets within the tumor. Both CD8⁺ and CD4⁺ T cells can be detected in most mesothelioma patients, and the beneficial role of tumor-infiltrating lymphocytes has been established in a range of different cancers [41].

The gene *TBC1D10C* [42] encodes the immune protein carabin which is capable of negatively regulating both Ras signaling and calcineurin, inhibiting both T cells [43] and B cells [44]. Despite its inhibitory role in immune cells, this gene has been found to have a strong positive correlation with infiltrating immune cells, including CD8⁺ T cells and activated B cells. In a study of breast cancer patients, this gene was identified to correlate with both overall survival and progression-free survival [45]. The potential for a beneficial effect of recruited immune cells is echoed by this study's finding that high levels of the gene encoding the protease granzyme A (*GZMA*) are also associated with improved survival. Expressed in cytotoxic lymphocytes (primarily CD8⁺ T cells and NK cells), granzyme A is a member of the serine protease family of granzymes and promotes anti-tumor activity via the induction of programmed cell death. The evaluation of the expression level of this gene has been used, together with perforin (*PRF1*), as a measure of the cytolytic activity (CYT) present within a tumor [46]. Although a recent meta-analysis found that there was large amounts of tumor heterogeneity in the level of CYT and that the prognostic value of this parameter is complicated by other factors in the tumor microenvironment [47], this study supports a protective, rather than tumor-permissive, role for increased immune activity within the mesothelioma tumor environment.

Drug repurposing against the five genes identified to influence patient survival led to a total of six putative drugs being identified that may have therapeutic benefit in mesothelioma. As highlighted in the Results, only one drug—disulfiram—returned a specifically-focused research article in the context of mesothelioma [26]. In this study, copper-complexed dithiocarbamate compound disulfiram (DSF-Cu) was shown to be cytotoxic in a panel of five human MPM cell lines. This panel included mesothelioma cell lines that were epithelioid, biphasic, and sarcomatoid in nature, indicating a potential wider use of the drug. This is key, as the histology of mesothelioma is associated with prognosis, with sarcomatoid being linked to a poorer prognosis [1]. The drug also showed efficacy on a mouse MPM allograft [26].

A 2017 conference paper from the National Cancer Research Institute Cancer Conference highlighted that disulfiram in combination with copper was cytotoxic in mesothelioma cells and curative at the in vivo level [48]. The same conference paper highlighted that disulfiram in combination with copper abolished PD-L1 expression in mesothelioma cells, which provides further rationale for its use in combination with PD-1/PD-L1 immune checkpoint blockade, as posited herein.

A recent review on drug repurposing in mesothelioma [49] did discuss disulfiram, though in the context of mesothelioma, only the article by Cheriyan et al. (2014) was discussed. This further highlights the relative infancy of investigation of disulfiram in mesothelioma, signposting a need for further studies to confirm its effects.

As shown in Table 1, disulfiram was the only drug to return specific results for having been tested in mesothelioma. The remaining five drugs (terfenadine, maraviroc, clioquinol, chloroxine, and oxyphenbutazone) did not return search results and are, therefore, under-investigated in the context of mesothelioma. They have, however, been tested in a variety of other cancers, as discussed below, and an expanded literature search identified one drug screening article that investigated both disulfiram and terfenadine [50].

Terfenadine, an antihistamine, has been tested in several cancers and the use of antihistamines in cancer in general has been previously reviewed [51]. Terfenadine has shown efficacy in human melanoma [52–54], human mast cell leukemic cells [55], breast cancer [56], prostate cancer [57], and non-small cell lung cancer [58]. The drug screening study that assessed terfenadine in mesothelioma [50] highlighted it as having defined cytotoxic potential against a panel of mesothelioma cell lines. Though disulfiram was

also assayed, it demonstrated less potential than a significant number of other drugs assessed [50].

Maraviroc, an antiretroviral CCR5 antagonist [59], has been tested in cancers, including breast [60], gastric [61], and colorectal cancers [62]. Maraviroc has recently been tested in 2022 in a phase one clinical trial, where it was combined with pembrolizumab (anti-PD-1) in refractory mismatch repair proficient/microsatellite-stable metastatic colorectal cancer [63]. In this study, the combination therapy was feasible and demonstrated a beneficial toxicity pattern [63]. Clioquinol, an antifungal and antiprotozoal drug [64], has been tested in a variety of cancers and shown efficacy at the preclinical level, though low efficacy was demonstrated in a clinical trial [65]. This prompted studies into alternative applications and combinations of clioquinol-based therapy [65].

The anticancer efficacies of chloroxine and oxyphenbutazone have also been investigated, with chloroxine restoring platinum sensitivity in high-grade serous ovarian cancer cells [66] and oxyphenbutazone promoting cytotoxicity in hepatocellular carcinoma at the in vitro and in vivo level [67].

It is important to note that there are several limitations to this study. Most principally, the analyses have only been conducted on a single patient cohort of mesothelioma patients. This limitation is one that arises quite naturally in mesothelioma as a result of its rarity and understudied nature. Additionally, as highlighted in a previous study [12], patient-level omics analyses are increasingly moving towards the integration of multi-omics datasets [6] to allow for the capture of information flow along several levels of biology. However, as an initial exploratory study, such analysis was considered beyond the scope of this article. Further studies are needed to independently validate the findings presented in this article in another patient cohort and through the integration of multi-omics data.

Building on the patient survival-associated discoveries at the mRNA level, this study identified numerous putative repurposed drugs for use in mesothelioma. Although no drugs other than disulfiram and terfenadine have been studied in the context of mesothelioma, the fact remains that the consistent methodology used to identify these drugs validates the panel as potential treatments for mesothelioma. However, further studies and building a solid preclinical rationale for their use are, of course, required, as is the delineation of their solo efficacy and their prospective use as adjuvants to immune checkpoint blockade. A rational starting point to investigate these drugs would be basic cell viability assays, such as an SRB or MTS approach, which would identify any standalone cytotoxic effect in mesothelioma cells [68]. One way to then take this forward would be animal studies where the putative immunotherapeutic adjuvants are used in conjunction with anti-PD-1/anti-PD-L1 therapy. One example of a model that could be used for this would be the AB1-HA murine mesothelioma model [69,70]. Should these experiments yield promising results, clinical trials could be designed which, provided the use of effective endpoints and design, could provide novel treatment combinations for this underserved patient population.

5. Conclusions

This study has validated a previously identified *CD274/PDCD1*-related network in the context of mesothelioma. Of the 42 genes screened, only 5 genes demonstrated a significant survival association, whereas drug repurposing against the 5 genes led to 6 drugs being identified as potential immune checkpoint adjuvants for mesothelioma. Though evidence is lacking for the use of most of these drugs in mesothelioma (either alone or as immunotherapeutic adjuvants), the demonstrated efficacy of disulfiram and terfenadine validates the method used to identify the drugs. Future in vitro studies are required to determine cytotoxicity in mesothelioma, as well as the molecular mechanisms of any identified efficacy.

Supplementary Materials: The following supporting information can be downloaded at: <https://www.mdpi.com/article/10.3390/biomedinformatics2040037/s1>, Figure S1: Distribution of p-values from Kaplan–Meier plots for CD274, PDCD1, and 40 PDCD1/CD274-related genes; Figure S2: Co-expression analysis of PDCD1 and CD274 with CCR5; Figure S3: Co-expression analysis of PDCD1 and CD274 with GATD3; Figure S4: Co-expression analysis of PDCD1 and CD274 with CXCR6; Figure S5: Co-expression analysis of PDCD1 and CD274 with GZMA; Figure S6: Co-expression analysis of PDCD1 and CD274 with TBC1D10C; Table S1: Kaplan–Meier curve p-values obtained from cBioPortal and Benjamini–Hochberg adjusted p-values; Table S2: Node degree distribution for the PDCD1/CD274 network as identified by STRING analysis.

Author Contributions: Conceptualization, G.M.O. and E.Y.B.; methodology, G.M.O. and E.Y.B.; software, G.M.O. and E.Y.B.; validation, G.M.O. and E.Y.B.; formal analysis, G.M.O. and E.Y.B.; investigation, G.M.O. and E.Y.B.; resources, G.M.O. and E.Y.B.; data curation, G.M.O. and E.Y.B.; writing—original draft preparation, G.M.O. and E.Y.B.; writing—review and editing, G.M.O. and E.Y.B.; visualization, G.M.O. and E.Y.B.; project administration, G.M.O. and E.Y.B. All authors have read and agreed to the published version of the manuscript.

Funding: This research received no external funding.

Institutional Review Board Statement: Not applicable.

Informed Consent Statement: Not applicable.

Data Availability Statement: All data accessed in this study are available on multiple publicly available databases, as described in Materials and Methods.

Conflicts of Interest: The authors declare no conflict of interest.
